HITTING-SETS FOR ROABP AND SUM OF SET-MULTILINEAR CIRCUITS

MANINDRA AGRAWAL, ROHIT GURJAR, ARPITA KORWAR, AND NITIN SAXENA

Abstract. We give a \( n^{O(\log n)} \)-time \((n \text{ is the input size})\) blackbox polynomial identity testing algorithm for unknown-order read-once oblivious arithmetic branching programs (ROABP). The best time-complexity known for blackbox PIT for this class was \( n^{O(\log^2 n)} \) due to Forbes-Saptharishi-Shpilka (STOC 2014). Moreover, their result holds only when the individual degree is small, while we do not need any such assumption. With this, we match the time-complexity for the unknown order ROABP with the known order ROABP (due to Forbes-Shpilka (FOCS 2013)) and also with the depth-3 set-multilinear circuits (due to Agrawal-Saha-Saxena (STOC 2013)). Our proof is simpler and involves a new technique called basis isolation.

The depth-3 model has recently gained much importance, as it has become a stepping stone to understanding general arithmetic circuits. Multilinear depth-3 circuits are known to have exponential lower bounds but no polynomial time blackbox identity tests. In this paper, we take a step towards designing such hitting-sets. We give the first subexponential whitebox PIT for the sum of constantly many set-multilinear depth-3 circuits. To achieve this, we define the notions of distance and base sets. Distance, for a multilinear depth-3 circuit (say, in \( n \) variables and \( k \) product gates), measures how far are the variable partitions corresponding to the product gates, from being a mere refinement of each other. The 1-distance circuits strictly contain the set-multilinear model, while \( n \)-distance captures general multilinear depth-3. We design a hitting-set in time \( (nk)^{O(\Delta \log n)} \) for \( \Delta \)-distance. Further, we give an extension of our result to models where the distance is large (close to \( n \)) but it is small when restricted to certain base sets (of variables).

We also explore a new model of read-once arithmetic branching programs (ROABP) where the factor-matrices are invertible (called invertible-factor ROABP). We design a hitting-set in time \( \text{poly}(n^w) \) for width-\( w \) invertible-factor ROABP. Further, we could do without the invertibility restriction when \( w = 2 \). Previously, the best result for width-2 ROABP was quasi-polynomial time (Forbes-Saptharishi-Shpilka, STOC 2014).

1. Introduction. The problem of Polynomial Identity Testing is that of deciding if a given polynomial is zero. The complexity of the question depends crucially on the way the polynomial is input to the PIT test. For example, if the polynomial is given as a set of coefficients of the monomials, then we can easily check whether the polynomial is nonzero in polynomial time. The problem has been studied for different input models. Most prominent among them is the model of arithmetic circuits. Arithmetic circuits are the arithmetic analog of boolean circuits. Arithmetic circuits are the arithmetic analog of boolean circuits and are defined over a field \( \mathbb{F} \). They are directed acyclic graphs, where every node is a ‘+’ or ‘\( \times \)’ gate and each input gate is a constant from the field \( \mathbb{F} \) or a variable from \( x = \{ x_1, x_2, \ldots, x_n \} \). Every edge has a weight from the underlying field \( \mathbb{F} \). The computation is done in the natural way. Clearly, the output gate computes a polynomial in \( \mathbb{F}[x] \). We can restate the PIT problem as: Given an arithmetic circuit \( C \), decide if the polynomial computed by \( C \) is zero, in time polynomial in the circuit size. Note that, given a circuit, computing the polynomial explicitly is not possible in poly-time, as it can have exponentially many monomials. However, given the circuit, it is easy to compute an evaluation of the polynomial by substituting the variables with constants.

Though there is no known deterministic algorithm for PIT, there are easy randomized algorithms [DL78, Zip79, Sch80]. These randomized algorithms are based on the theorem: A nonzero polynomial, evaluated at a random point, gives a nonzero value with a good probability. Observe that such an algorithm does not need to access the structure of the circuit, it just uses the evaluations; it is a blackbox algorithm. The other kind of algorithms, where the structure of the input is used, are called whitebox algorithms. Whitebox algorithms for PIT have many known applications. E.g. graph matching reduces to PIT. On the other hand, blackbox algorithms (or
hitting-sets) have connections to circuit lower bound proofs. PIT also fits well in the
game complexity theory framework, see [Mul12b, Mul12a]. See the surveys by
Saxena [Sax09, Sax14] and Shpilka & Yehudayoff [SY10] for more applications.

An Arithmetic Branching Program (ABP) is another interesting model for com-
puting polynomials. It consists of a directed acyclic graph with a source and a sink.
The edges of the graph have polynomials as their weights. The weight of a path is the
product of the weights of the edges present in the path. The polynomial computed
by the ABP is the sum of the weights of all the paths from the source to the sink.
It is well known that for an ABP, the underlying graph can seen as a layered graph
such that all paths from the source to the sink have exactly one edge in each layer.
And the polynomial computed by the ABP can be written as a matrix product, where
each matrix corresponds to a layer. The entries in the matrices are weights of the
 corresponding edges. The maximum number of vertices in a layer, or equivalently, the
dimension of the corresponding matrices is called the width of the ABP. It is known
that projections of symbolic determinant and ABPs have the same expressive power
[Ber84, Tod91, MV97]. Ben-Or & Cleve [BOC92] have shown that a polynomial com-
puted by a formula can also be computed by a width-3 ABP of size polynomial in the
formula size. A formula is a circuit with every node (except the input gates) having
outdegree at most 1. Thus, ABP is a strong model for computing polynomials. The
following chain of reductions shows the power of ABP and its constant-width version
relative to other arithmetic computation models (see [BOC92] and [Nis91, Lemma 1]).

\[
\text{Constant-depth Arithmetic Circuits} \leq_p \text{Constant-width ABP} \\
=\_p \text{Formulas} \leq_p \text{ABP} \leq_p \text{Arithmetic Circuits}
\]

Our first result is for a special class of ABP called Read Once Oblivious Arithmetic
Branching Programs (ROABP). An ABP is a read once ABP (ROABP) if the weights
in its \(n\) layers are univariate polynomials in \(n\) distinct variables, i.e. the \(i\)-th layer
has weights coming from \(\mathbb{F}[x_{\pi(i)}]\), where \(\pi\) is a permutation on the set \(\{1, 2, \ldots, n\}\).
When we know this permutation \(\pi\), we call it an ROABP with known variable order
(it is significant only in the blackbox setting).

Raz and Shpilka [RS05] gave a poly\((n, w, \delta)\)-time whitebox algorithm for \(n\)-variate
polynomials computed by a width-\(w\) ROABP with individual degree bound \(\delta\). Re-
cently, Forbes and Shpilka [FS12, FS13] gave a poly\((n, w, \delta \log n)\)-time blackbox algo-
rithm for the same, when the variable order is known. Subsequently, Forbes et al.
[FSS14] gave a blackbox test for the case of unknown variable order, but with time
complexity being poly\((n)^{\delta \log w \log n}\). Note the exponential dependence on the degree.
Their time complexity becomes quasi-polynomial in case of multilinear polynomials
i.e. \(\delta = 1\) (in fact, even when \(\delta = \text{poly}(\log n)\)).

In another work Jansen et al. [JQS10b] gave quasi-polynomial time blackbox test
for a sum of constantly many multilinear “ROABP”. Their definition of “ROABP” is
more stringent. They assume that every variable appears at most once in the ABP.
Later, this result was generalized to “read-r OABB” [JQS10a], where a variable can
occur in at most one layer, and on at most \(r\) edges. Our definition of ROABP seems
much more powerful than both of these.

We improve the result of [FSS14] and match the time complexity for the unknown
order case with the known order case (given by [FS12, FS13]). Unlike [FSS14], we do
not have exponential dependence on the individual degree. Formally,

**Theorem 1.** Let \(C(\mathbf{x})\) be an \(n\)-variate polynomial computed by a width-\(w\) ROABP
(unknown order) with the degree of each variable bounded by $\delta$. Then there is a $\text{poly}(n, w, \delta) \log n$-time hitting set for $C$.

**Remark.** Our algorithm also works when the layers have their weights as general sparse polynomials (still over disjoint sets of variables) instead of univariate polynomials (see the detailed version in Section 3).

A polynomial computed by a width-$w$ ABP can be written as $S^\top D(x)T$, where $S, T \in F^w$ and $D(x) \in F^{w \times w}[x]$ is a polynomial over the matrix algebra. Like [ASS13, FSS14], we try to construct a basis (or extract the rank) for the coefficient vectors in $D(x)$. We actually construct a weight assignment on the variables, which “isolates” a basis in the coefficients in $D(x)$. This idea is inspired from the rank extractor techniques in [ASS13, FSS14]. Our approach is to directly work with $D(x)$, while [ASS13, FSS14] have applied a rank extractor to small subcircuits of $D(x)$ by shifting it carefully. In fact, the idea of “basis isolating weight assignment” evolved when we tried to find a direct proof for the rank extractor in [ASS13], which does not involve subcircuits. But, our techniques go much further than both [ASS13, FSS14], as is evident from our strictly better time-complexity results.

The boolean analog of ROABP, read once ordered branching programs (ROBP) have been studied extensively, with regard to the RL vs. L question. For ROBP, a pseudorandom generator (PRG) with seed length $O(\log^2 n)$ ($n^{O(\log n)}$ size sample space) is known in the case of known variable order [Nis90]. This is analogous to the [FS13] result for known order ROABP. On the other hand, in the unknown order case, the best known seed length is of size $n^{1/2+o(1)}$ ($2^{n^{1/2+o(1)}}$ size sample space) [IMZ12]. One can ask: Can the result for the unknown order case be matched with the known order case in the boolean setting as well. Recently, there has been a partial progress in this direction by [SVW14].

The PIT problem has also been studied for various restricted classes of circuits. One such class is depth-3 circuits. Our second result is about a special case of this class. A depth-3 circuit is usually defined as a $\Sigma \Pi \Sigma$ circuit: The circuit gates are in three layers, the top layer has an output gate which is $+$, second layer has all $\times$ gates and the last layer has all $+$ gates. In other words, the polynomial computed by a $\Sigma \Pi \Sigma$ circuit is of the form $C(x) = \sum_{i=1}^{k} a_i \prod_{j=1}^{n_i} \ell_{ij}$, where $n_i$ is the number of input lines to the $i$-th product gate and $\ell_{ij}$ is a linear polynomial of the form $b_0 + \sum_{r=1}^{n} b_r x_r$. An efficient solution for depth-3 PIT is still not known. Recently, it was shown by Gupta et al. [GKKS13], that depth-3 circuits are almost as powerful as general circuits. A polynomial time hitting-set for a depth-3 circuit implies a quasi-poly-time hitting-set for general poly-degree circuits. Till now, for depth-3 circuits, efficient PIT is known when the top fan-in $k$ is assumed to be constant [DS07, KS07, KS09, KS11, SS11, SS12, SS13] and for certain other restrictions [Sax08, SSS13, ASSS12].

On the other hand, there are exponential lower bounds for depth-3 *multilinear* circuits [RY09]. Since there is a connection between lower bounds and PIT [Agr05], we can hope that solving PIT for depth-3 multilinear circuits should also be feasible. This should also lead to new tools for general depth-3.

A polynomial is said to be multilinear if the degree of every variable in every term is at most 1. The circuit $C(x)$ is a multilinear circuit if the polynomial computed at every gate is multilinear. A polynomial time algorithm is known only for a sub-class of multilinear depth-3 circuits, called depth-3 *set-multilinear circuits*. This algorithm is due to Raz and Shpilka [RS05] and is whitebox. In a depth-3 multilinear circuit, since every product gate computes a multilinear polynomial, a variable occurs in at most one of the linear polynomials input to it. Thus, each product gate naturally induces
a partition of the variables, where each color (i.e. part) of the partition contains the variables present in a linear polynomial. Further, if the partitions induced by all the product gates are the same then the circuit is called a depth-3 set-multilinear circuit.

Agrawal et al. [ASS13] gave a quasi-polynomial time blackbox PIT for the class of depth-3 set-multilinear circuits. But before this work, no subexponential time PIT (not even whitebox) was known even for sum of two set-multilinear circuits. We give a subexponential time whitebox PIT for sum of constantly many set-multilinear circuits (also, see subsequent work).

**Theorem 2.** Let \( C(x) \) be a \( n \)-variate polynomial, which is a sum of \( c \) set-multilinear depth-3 circuits, each having top fan-in \( k \). Then there is an \( n^{O(n^{1-\epsilon} \log k)} \)-time whitebox test for \( C \), where \( \epsilon := 1/2^{c-1} \).

To achieve this, we define a new class of circuits, as a tool, called multilinear depth-3 circuits with \( \Delta \)-distance. A multilinear depth-3 circuit has \( \Delta \)-distance if there is an ordering on the partitions induced by the product gates, say \( (P_1, P_2, \ldots, P_k) \), such that for any color in the partition \( P_i \), there exists a set of \( \leq (\Delta - 1) \) other colors in \( P_i \) such that the set of variables in the union of these \( \leq \Delta \) colors are exactly partitioned in the upper partitions, i.e. \( \{P_1, P_2, \ldots, P_{i-1}\} \). As we will see, such sets of \( \Delta \) colors form equivalence classes of the colors at partition \( P_i \). We call them friendly neighborhoods and they help us in identifying subcircuits. Intuitively, the distance measures how far away are the partitions from a mere refinement sequence of partitions, \( P_1 \leq P_2 \leq \cdots \leq P_k \). A refinement sequence of partitions will have distance 1. On the other hand, general multilinear depth-3 circuits can have at most \( n \)-distance.

As it turns out, a polynomial computed by a depth-3 \( \Delta \)-distance circuit (top fan-in \( k \)) can also be computed by a width-\( O(kn\Delta) \) ROABP (see Lemma 14). Thus, we get a \( \text{poly}(nk)^{\Delta \log n} \)-time hitting set for this class, from Theorem 1. Next, we use a general result about finding a hitting set for a class \( m \)-base-sets-\( \Delta \)-distance, if a hitting set is known for class \( C \). A polynomial is in \( m \)-base-sets-\( C \), if there exists a partition of the variables into \( m \) base sets such that restricted to each base set (treat other variables as the function field constants), the polynomial is in class \( C \). We combine these two tools to prove Theorem 2. We show that a sum of constantly many set-multilinear circuits falls into the class \( m \)-base-sets-\( \Delta \)-distance, for \( m\Delta = o(n) \).

Agrawal et al. [AGKS13] had achieved rank concentration, which implies a hitting set, for the class \( m \)-base-sets-\( \Delta \)-distance, but through complicated proofs. On the other hand, this work gives only a hitting set for the same class, but with the advantage of simplified proofs.

Our third result deals again with arithmetic branching programs. The results of [BOC92] and [SSS09] show that the constant-width ABPs capture several natural subclasses of circuits. Here, we study constant-width ABP with some natural restrictions.

We consider a class of ROABPs where all the matrices in the matrix product are invertible. We give a blackbox test for this class of ROABP. In contrast to [FSS14] and our Theorem 1, this test works in polynomial time if the dimension of the matrices is constant.

Note that the class of ABP, where the factor matrices are invertible, is quite powerful, as Ben-Or and Cleve [BOC92] actually reduce formulas to width-3 ABP with invertible factors. Saha, Saptharishi and Saxena [SSS09] reduce depth-3 circuits to width-2 ABP with invertible factors. But the constraints of invertibility

---

\[ \forall i, \text{each color in } P_i \text{ gets exactly partitioned in the upper partitions} \]
and read-once together seem to restrict the computing power of the ABP, making it amenable to this line of attack. Interestingly, an analogous class of read-once boolean branching programs called *permutation branching programs* has been studied recently [KNP11, De11, Ste12]. These works give PRG for this class (for constant width) with seed-length $O(\log n)$, in the known variable order case. In other words, they give polynomial size sample space which can fool these programs. For the unknown variable order case, Reingold et al. [RSV13] gave a PRG with seed-length $O(\log^2 n)$. Our polynomial size hitting sets work for any unknown variable order, hence, it is better as compared to the currently known results for the arithmetic setting work for any unknown variable order. For the unknown variable order case, Reingold et al. [RSV13] gave a PRG with seed-length $O(\log n)$. These works give PRG for this class (for constant width) with seed-length $O(\log n)$ [KNP11, De11, Ste12]. \(F^{m \times n}\) represents the set of all \(m \times n\) matrices over the field \(F\). \(M_{m \times n}(F)\) will
denote the algebra of \(m \times m\) matrices over the field \(F\). Let \(A_k(F)\) be any \(k\)-dimensional
algebra over the field \(F\). For any two elements \(A = (a_1, a_2, ..., a_k) \in A_k(F)\) and
\(B = (b_1, b_2, ..., b_k) \in A_k(F)\) (having a natural basis representation in mind), their dot
product is defined as \(A \cdot B = \sum_{i=1}^{n} a_k b_k\); and the product \(AB\) will denote the product
in the algebra \(A_k(F)\).

Part(S) denotes the set of all possible partitions of the set \(S\). Elements in a
partition are called colors (or parts).

2.2. Arithmetic Branching Programs. An ABP is a directed graph with
d \(+\) 1 layers of vertices \(\{V_0, V_1, ..., V_d\}\) and a start node \(u\) and an end node \(t\) such
that the edges are only going from \(u\) to \(V_0, V_{i-1}\) to \(V_i\) for any \(i \in [d]\), \(V_d\) to \(t\). A
width-\(w\) ABP has \(|V_i| \leq w\) for all \(i \in [d]\). Let the set of nodes in \(V_i\) be \(\{v_{i,j} \mid j \in [w]\}\).
All the edges in the graph have weights from \(F[x]\), for some field \(F\). As a convention,
the edges going from \(u\) and coming to \(t\) are assumed to have weights from the field \(F\).

For an edge \(e\), let us denote its weight by \(W(e)\). For a path \(p\) from \(u\) to \(t\), its weight
\(W(p)\) is defined to be the product of weights of all the edges in it, i.e. \(\prod_{e \in p} W(e)\).
Consider the polynomial \(C(x) = \sum_{p \in \text{paths}(u,t)} W(p)\) which is the sum of the weights
of all the paths from \(u\) to \(t\). This polynomial \(C(x)\) is said to be computed by the
ABP.

It is easy to see that this polynomial is the same as \(S^T(\prod_{i=1}^{d} D_i)T\), where \(S,T \in F^w\)
and \(D_i\) is a \(w \times w\) matrix for \(1 \leq i \leq d\) such that
\[
S(\ell) = W(u, v_{0,\ell}) \text{ for } 1 \leq \ell \leq w
\]
\[
D_i(k, \ell) = W(v_{i-1,k}, v_{i,\ell}) \text{ for } 1 \leq \ell, k \leq w \text{ and } 1 \leq i \leq d
\]
\[
T(k) = W(v_{d,k}, t) \text{ for } 1 \leq k \leq w
\]

ROABP. An ABP is called a read once oblivious ABP (ROABP) if the edge
weights in the different layers are univariate polynomials in distinct variables. Formally,
the entries in \(D_i\) come from \(F[x_{\pi(i)}]\) for all \(i \in [d]\), where \(\pi\) is a permutation
on the set \([d]\).

sparse-factor ROABP. We call the ABP a sparse-factor ROABP if the edge
weights in different layers are sparse polynomials in disjoint sets of variables. Formally,
if there exists an unknown partition of the variable set \(x\) into \(d\) sets \(\{x_1, x_2, ..., x_d\}\)
such that \(D_i \in F^{w \times w}[x_i]\) is a \(s\)-sparse polynomial, for all \(i \in [d]\), then the corresponding
ROABP is called a \(s\)-sparse-factor ROABP. It is read once in the sense that any
particular variable contributes to at most one edge on any path.

2.3. Kronecker Map. We will often use a weight function on the variables
which separates a desired set of monomials. It is a folklore trick to solve blackbox
PTT for sparse polynomials. The following lemma is used towards the end of proofs
of Theorem 1 and 3 to design the hitting-sets. Let \(w: x \mapsto N\) be a weight function on
the variables. Consider its natural extension to the set of all monomials \(w: \mathbb{Z}_+^n \to \mathbb{N}\) as follows:
\(w(\prod_{i=1}^{n} x_i^{\gamma_i}) = \sum_{i=1}^{n} \gamma_i w(x_i)\), where \(\gamma_i \in \mathbb{Z}_+, \forall i \in [n]\). Note that if each
variable \(x_i\) is replaced with \(t^{w(x_i)}\) then any monomial \(m\) just becomes \(t^{w(m)}\).

Lemma 4 (Efficient Kronecker map [Kro82, AB03]). Let \(M\) be the set of all
monomials in \(n\) variables \(x = \{x_1, x_2, ..., x_n\}\) with maximum individual degree \(\delta\). For
any value \(a\), there exists a (constructible) set of \(N \coloneqq n a \log(\delta + 1)\) weight functions
\(w: x \to \{1, ..., 2N \log N\}\), such that for any set \(A\) of pairs of monomials from \(M\)
with \(|A| = a\), at least one of the weight functions separates all the pairs in \(A\), i.e.
\(\forall (m, m') \in A, w(m) \neq w(m')\) (proof is described in Appendix A).
3. Hitting set for ROABP: Theorem 1. Like [ASS13] and [FSS14], we work with the vector polynomial. That is, for a polynomial computed by a width-$w$ ROABP, $C(x) = S^T(\prod_{i=1}^{d} D_i)T$, we see the product $D := \prod_{i=1}^{d} D_i$ as a polynomial over the matrix algebra $\mathbb{M}_{w \times w}(\mathbb{F})$. We can write the polynomial $C(x)$ as the dot product $R \cdot D$, where $R = ST^T$. The vector space spanned by the coefficients of $D(x)$ is called the coefficient space of $D(x)$. This space will have dimension at most $w^2$. We essentially try to construct a small set of vectors, by evaluating $D(x)$, which can span the coefficient space of $D(x)$. Clearly, if $C \neq 0$ then the dot product of $R$ with at least one of these spanning vectors will be nonzero. And thus, we get a hitting set.

Unlike [ASS13] and [FSS14], we directly work with the original polynomial $D(x)$, instead of shifting it and breaking it into subcircuits. For a polynomial in $\mathbb{F}[x]$, a usual technique for PIT is to give a univariate monomial map for the variables, such that a monomial of the given polynomial is isolated (e.g. sparse PIT [KS01]). Our approach can be seen as a generalization of this technique. We come up with a univariate map (or weight function) on the variables which can isolate a basis for the coefficients of the polynomial $D(x) \in \mathbb{M}_{w \times w}[x]$.

We present our results for polynomials over arbitrary algebra. Let $\mathbb{A}_k(\mathbb{F})$ be a $k$-dimensional algebra over the field $\mathbb{F}$. Let $x = \{x_1, x_2, \ldots, x_n\}$ be a set of variables and let $D(x)$ be a polynomial in $\mathbb{A}_k(\mathbb{F})[x]$ with highest individual degree $\delta$. Let $\mathcal{M}$ denote the set of all monomials over the variable set $x$ with highest individual degree $\delta$.

Now, we will define a basis isolating weight assignment for a polynomial $D \in \mathbb{A}_k(\mathbb{F})[x]$ which would lead to a hitting set for the polynomial $C \in \mathbb{F}[x]$, where $C = R \cdot D$, for some $R \in \mathbb{A}_k(\mathbb{F})$.

**Definition 5 (Basis Isolating Weight Assignment).** A weight function $w: \mathbb{N}$ is called a basis isolating weight assignment for a polynomial $D(x) \in \mathbb{A}_k(\mathbb{F})[x]$ if there exists a set of monomials $S \subseteq \mathcal{M}$ ($k' := |S| \leq k$) whose coefficients form a basis for the coefficient space of $D(x)$, such that

- for any $m, m' \in S$, $w(m) \neq w(m')$ and
- for any monomial $m \in \mathcal{M} \setminus S$, $\text{coef}_D(m) \in \text{span}\{\text{coef}_D(m') \mid m' \in S, w(m') < w(m)\}$.

The above definition is equivalent to saying that there exists a unique minimum weight basis (according to the weight function $w$) among the coefficients of $D$, and also the basis monomials have distinct weights. We skip the easy proof for this equivalence, as we will not need it. Let us emphasize here that according to this definition there could be many monomials in $\mathcal{M} \setminus S$ which have the same weight as a monomial $m$ in $S$. The only requirement is that their coefficients should be linearly dependent on basis coefficients with weight smaller than $w(m)$.

Note that a weight assignment, which gives distinct weights to all the monomials, is indeed a basis isolating weight assignment. But, it will involve exponentially large weights. To find an efficient weight assignment one must use some properties of the given circuit. First, we show how such a weight assignment would lead to hitting set. We will actually show that it isolates a monomial in $C(x)$.

**Lemma 6.** Let $w: \mathbb{N}$ be a basis isolating weight assignment for a polynomial $D(x) \in \mathbb{A}_k(\mathbb{F})[x]$. And let $C = R \cdot D$ be a nonzero polynomial, for some $R \in \mathbb{A}_k(\mathbb{F})$. Then, after the substitution $x_i = t^{w(x_i)}$ for all $i \in [n]$, the polynomial $C$ remains nonzero, where $t$ is an indeterminate.

**Proof.** For any monomial $m \in \mathcal{M}$, let $D_m \in \mathbb{A}_k(\mathbb{F})$ denote the coefficient
Hence, it is easy to see that after the mentioned substitution, the new polynomial $C'(t)$ is equal to $\sum_{m \in \mathcal{M}} (R \cdot D_m) w(m)$.

Let us say that $S \subseteq \mathcal{M}$ is the set of monomials whose coefficients form the isolated basis for $D$. According to the definition of the basis isolating weight assignment, for any monomial $m \in \mathcal{M} \setminus S$,

$$D_m \in \text{span}\{D_{m'} \mid m' \in S, \; w(m') < w(m)\}. \tag{1}$$

First, we claim that $\exists m' \in S$ such that $R \cdot D_{m'} \neq 0$. For the sake of contradiction, let us assume that $\forall m' \in S$, $R \cdot D_{m'} = 0$. Taking the dot product with $R$ on both the sides of Equation (1), we get that for any monomial $m \in \mathcal{M} \setminus S$,

$$R \cdot D_m \in \text{span}\{R \cdot D_{m'} \mid m' \in S, \; w(m') < w(m)\}.$$

Hence, $R \cdot D_m = 0$, $\forall m \in \mathcal{M}$. That means $C(x) = 0$, which contradicts our assumption.

Now, let $m^*$ be the minimum weight monomial in $S$ whose coefficient gives a nonzero dot product with $R$, i.e. $m^* = \arg \min_{m \in S} \{w(m) \mid R \cdot D_m \neq 0\}$. There is a unique such monomial in $S$ because all the monomials in $S$ have distinct weights.

We claim that $\text{coef}_{C'}(t^{w(m^*)}) \neq 0$ and hence $C'(t) \neq 0$. To see this, consider any monomial $m$, other than $m^*$, with $w(m) = w(m^*)$. The monomial $m$ has to be in the set $\mathcal{M} \setminus S$, as the monomials in $S$ have distinct weights. From Equation (1),

$$D_m \in \text{span}\{D_{m'} \mid m' \in S, \; w(m') < w(m^*)\}.$$

Taking dot product with $R$ on both the sides we get,

$$R \cdot D_m \in \text{span}\{R \cdot D_{m'} \mid m' \in S, \; w(m') < w(m^*)\}.$$

But, by the choice of $m^*$, $R \cdot D_{m'} = 0$, for any $m' \in S$ with $w(m') < w(m^*)$. Hence, $R \cdot D_m = 0$, for any $m \neq m^*$ with $w(m) = w(m^*)$.

So, the coefficient $\text{coef}_{C'}(t^{w(m^*)})$ can be written as

$$\sum_{m \in \mathcal{M} \atop w(m) = w(m^*)} R \cdot D_m = R \cdot D_{m^*},$$

which, we know, is nonzero. $\Box$

We continue to use $C'$ and $S$ as in the proofs of Lemma 6. To construct a hitting set for $C'(t)$, we can try many possible field values for $t$. The number of such values needed will be the degree of $C'(t)$, which is at most $(n \max_i w(x_i))$. Hence, the cost of the hitting set is dominated by the cost of the weight function, i.e. the maximum weight given to any variable and the time taken to construct the weight function.

In the next step, we show that such a basis isolating weight assignment can indeed be found for a sparse-factor ROABP, but with cost quasi-polynomial in the input size. First, we make the following observation that it suffices that the coefficients of the monomials not in $S$, linearly depend on any coefficients with strictly smaller weight, not necessarily coming from $S$.

**Observation 7.** If, for a polynomial $D \in \mathbb{A}_k(\mathbb{F})[x]$, there exists a weight function $w: \mathbb{X} \rightarrow \mathbb{N}$ and a set of monomials $S \subseteq \mathcal{M}$ ($k':= |S| \leq k$) such that for any monomial $m \in \mathcal{M} \setminus S$,

$$\text{coef}_D(m) \in \text{span}\{\text{coef}_D(m') \mid m' \in \mathcal{M}, \; w(m') < w(m)\}$$

then we can also conclude that for any monomial \( m \in \mathcal{M} \setminus S \),
\[
\text{coef}_D(m) \in \text{span}\{\text{coef}_D(m') \mid m' \in S, \ w(m') < w(m)\}.
\]

**Proof.** We are given that for any monomial \( m \in \overline{S} := \mathcal{M} \setminus S \),
\[
\text{coef}_D(m) \in \text{span}\{\text{coef}_D(m') \mid m' \in \mathcal{M}, \ w(m') < w(m)\}.
\]
Any coefficient \( \text{coef}_D(m') \) on the right hand side of this equation, which corresponds to an index in \( \overline{S} \), can be replaced with some other coefficients, which have further smaller weight. If we keep doing this, we will be left with the coefficients only corresponding to the set \( S \), because in each step we are getting smaller and smaller weight coefficients.

In our construction of the weight function, we will create the set \( \overline{S} := \mathcal{M} \setminus S \) incrementally, i.e. in each step we will make more coefficients depend on strictly smaller weight coefficients. Finally, we will be left with only \( k' \) (the rank of the coefficient space of \( D \)) coefficients in \( S \). We present the result for an arbitrary \( k \)-dimensional algebra \( \mathbb{A}_k(\mathbb{F}) \), instead of just the matrix algebra.

**Lemma 8 (Weight Construction).** Let \( \mathbf{x} \) be given by a union of \( d \) disjoint sets of variables \( \mathbf{x}_1 \sqcup \mathbf{x}_2 \sqcup \cdots \sqcup \mathbf{x}_d \), with \( |\mathbf{x}| = n \). Let \( D(\mathbf{x}) = P_1(\mathbf{x}_1)P_2(\mathbf{x}_2) \cdots P_d(\mathbf{x}_d) \), where \( P_i \in \mathbb{A}_k(\mathbb{F})[\mathbf{x}_i] \) is a sparsity-\( s \), individual degree-\( \delta \) polynomial, for all \( i \in [d] \). Then, we can construct a basis isolating weight assignment for \( D(\mathbf{x}) \) with the cost being \( (\text{poly}(k,s,n,\delta))^{\log d} \).

**Proof.** In our construction, the final weight function \( w \) will be a combination of \( (\log d + 1) \) different weight functions, say \( (w_0, w_1, \ldots, w_{\log d}) \). The weight function \( w \) is said to be an ordering on the monomials which comes from the lexicographic ordering given by the weight functions \( (w_0, w_1, \ldots, w_{\log d}) \). Let us say, their precedence is decreasing from left to right, i.e. \( w_0 \) has the highest precedence and \( w_{\log d} \) has the lowest precedence. As mentioned earlier, we will build the set \( \overline{S} \) (the set of monomials whose coefficients are in the span of strictly smaller weight coefficients than themselves) incrementally in \( (\log d + 1) \) steps, using weight function \( w_i \) in the \( (i+1) \)-th step.

Let \( \mathcal{M}_{0,1}, \mathcal{M}_{0,2}, \ldots, \mathcal{M}_{0,d} \) be the sets of monomials and \( C_{0,1}, C_{0,2}, \ldots, C_{0,d} \) be the sets of coefficients in the polynomials \( P_1, P_2, \ldots, P_d \), respectively.

**Notation.** The product of two sets of monomials \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \) is defined as \( \mathcal{M}_1 \times \mathcal{M}_2 = \{m_1m_2 \mid m_1 \in \mathcal{M}_1, \ m_2 \in \mathcal{M}_2\} \). The product of any two sets of coefficients \( C_1 \) and \( C_2 \) is defined as \( C_1 \times C_2 = \{c_1c_2 \mid c_1 \in C_1, \ c_2 \in C_2\} \).

The crucial property of the polynomial \( D \) is that the set of coefficients in \( D, C_0 \), is just the product \( C_{0,1} \times C_{0,2} \times \cdots \times C_{0,d} \). Similarly, the set of all the monomials in \( D, \mathcal{M}_0 \), can be viewed as the product \( \mathcal{M}_{0,1} \times \mathcal{M}_{0,2} \times \cdots \times \mathcal{M}_{0,d} \). Let \( m := m_1m_{a+1} \cdots m_b \) be a monomial, where \( 1 \leq a \leq b \leq d \) and \( m_j \in \mathcal{M}_{0,j} \), for \( a \leq j \leq b \). Then \( D_m \) will denote the coefficient \( \text{coef}_{P_a}(m_a)\text{coef}_{P_{a+1}}(m_{a+1}) \cdots \text{coef}_{P_b}(m_b) \).

**Iteration 0:** Let us fix \( w_0 : \mathbf{x} \rightarrow \mathbb{N} \) to be a weight function on the variables which gives distinct weights to all the monomials in \( \mathcal{M}_{0,i} \) for each \( i \in [d] \). As \( w_0 \) assigns distinct weights to these monomials, so does the weight function \( w \).

For each \( P_i \) we do the following:
- arrange the coefficients in \( C_{0,i} \) in increasing order of their weight according to \( w \) (or equivalently, according to \( w_0 \)),
- choose a maximal set of linearly independent coefficients, in a greedy manner, going from lower weights to higher weights.
The fact that the weight functions \( w_1, w_2, \ldots, w_{\log d} \) are not defined yet does not matter because \( w_0 \) has the highest precedence. The total order given to the monomials in \( \mathcal{M}_{0,i} \) by \( w_0 \) is the same as given by \( w \), irrespective of what the functions \( w_1, \ldots, w_{\log d} \) are chosen to be.

This gives us a basis for the coefficients of \( P_i \), say \( C_{0,i}' \). Let \( \mathcal{M}_{0,i}' \) denote the monomials in \( P_i \) corresponding to these basis coefficients. From the construction of the basis, it follows that for any monomial \( m \in \mathcal{M}_{0,i} \setminus \mathcal{M}_{0,i}' \),

\[
D_m \in \text{span}\{D_{m'} : m' \in \mathcal{M}_{0,i}' \text{, } w(m') < w(m)\}. \tag{2}
\]

Now, consider any monomial \( m \in \mathcal{M}_0 \) which is not present in the set \( \mathcal{M}_0' := \mathcal{M}_{0,1}' \times \mathcal{M}_{0,2}' \times \cdots \times \mathcal{M}_{0,d}' \). Let \( m = m_1 m_2 \cdots m_d \), where \( m_i \in \mathcal{M}_{0,i} \) for all \( i \in [d] \). We know that for at least one \( j \in [d] \), \( m_j \in \mathcal{M}_{0,j} \setminus \mathcal{M}_{0,j}' \). Then using Equation (2) we can write the following about \( D_m = D_{m_1} D_{m_2} \cdots D_{m_d} \),

\[
D_m \in \text{span}\{D_{m_1} \cdots D_{m_{j-1}} D_{m_j} D_{m_{j+1}} \cdots D_{m_d} : m'_j \in \mathcal{M}_{0,j}' \text{, } w(m'_j) < w(m_j)\}.
\]

This holds, because the algebra product is bilinear. Equivalently, for any monomial \( m \in \mathcal{M}_0 \setminus \mathcal{M}_0' \),

\[
D_m \in \text{span}\{D_{m'} : m' \in \mathcal{M}_0, w(m') < w(m)\}.
\]

This is true because

\[
w(m_1) + \cdots + w(m_j') + \cdots + w(m_d)< w(m_1) + \cdots + w(m_j) + \cdots + w(m_d) = w(m).
\]

Hence, all the monomials in \( \mathcal{M}_0 \setminus \mathcal{M}_0' \) can be put into \( \mathfrak{S} \), i.e. their corresponding coefficients depend on strictly smaller weight coefficients.

**Iteration 1:** Now, let us consider monomials in the set \( \mathcal{M}_0' = \mathcal{M}_{0,1}' \times \mathcal{M}_{0,2}' \times \cdots \times \mathcal{M}_{0,d}' \). Let the corresponding set of coefficients be \( C_0' := C_{0,1}' \times C_{0,2}' \times \cdots \times C_{0,d}' \).

Since, the underlying algebra \( \mathfrak{A}_k(\mathbb{F}) \) has dimension at most \( k \) and the coefficients in \( C_{0,i}' \) form a basis for \( C_{0,i} \), \( |M_{0,i}'| \leq k \), for all \( i \in [d] \). In the above product, let us make \( d/2 \) disjoint pairs of consecutive terms, and for each pair, multiply the two terms in it. Putting it formally, let us define \( C_{1,j} \) to be the product \( C_{0,2j-1}' \times C_{0,2j}' \) and similarly \( \mathcal{M}_{1,j} := \mathcal{M}_{0,2j-1} \times \mathcal{M}_{0,2j}' \), for all \( j \in [d/2] \) (if \( d \) is odd, we can make it even by multiplying the identity element of \( \mathfrak{A}_k(\mathbb{F}) \) in the end). Now, let \( C_1 := C_0' = \mathfrak{S}_{1,1} \times \mathfrak{S}_{1,2} \times \cdots \times \mathfrak{S}_{1,d} \) and \( \mathcal{M}_1 := \mathcal{M}_0' = \mathcal{M}_{1,1} \times \mathcal{M}_{1,2} \times \cdots \times \mathcal{M}_{1,d} \), where \( d_1 := d/2 \). For any \( i \in [d_1] \), \( \mathcal{M}_{1,i} \) has at most \( k^2 \) monomials.

Now, we fix the weight function \( w_1 : \mathbb{X} \to \mathbb{N} \) such that it gives distinct weights to all the monomials in \( \mathcal{M}_{1,i} \), for each \( i \in [d_1] \). As \( w_1 \) separates these monomials, so does the weight function \( w \). Now, we repeat the same procedure of constructing a basis in a greedy manner for \( C_{1,i} \) according to the weight function \( w \), for each \( i \in [d_1] \). Let the basis coefficients for \( C_{1,i} \) be \( C_{1,i}' \), and corresponding monomials be \( \mathcal{M}_{1,i}' \).

As argued before, any coefficient in \( C_{1,i} \), which is outside the set \( C_{1,i}' := C_{1,1}' \times C_{1,2}' \times \cdots \times C_{1,d_1}' \), is in the span of strictly smaller weight (than itself) coefficients. So, we can also put the corresponding monomials \( \mathcal{M}_{1,i} \setminus \mathcal{M}_{1,i}' \) in \( \mathfrak{S} \) where \( \mathcal{M}_{1,i}' := \mathcal{M}_{1,1}' \times \mathcal{M}_{1,2}' \times \cdots \times \mathcal{M}_{1,d_1}' \).

**Iteration r:** We keep repeating the same procedure for \( (\log d + 1) \) rounds. After round \( r \), say the set of monomials we are left with is given by the product \( \mathcal{M}_{r-1} := \mathcal{M}_{r-1,1}' \times \mathcal{M}_{r-1,2}' \times \cdots \times \mathcal{M}_{r-1,d_1-1}' \), where \( \mathcal{M}_{r-1,i} \) has at most \( k \) monomials, for each \( i \in [d_{r-1}] \) and \( d_{r-1} = d/2^{r-1} \). In the above product, we make \( d_{r-1}/2 \) disjoint
pairs of consecutive terms, and multiply the two terms in each pair. Let us say we get \( M_r := M'_{r-1} = M_{r-1} \times M_{r-2} \times \cdots \times M_{r_d} \), where \( d_r = d_{r-1}/2 \). Say, the corresponding set of coefficients is given by \( \mathcal{C}_r = C_{r,1} \times C_{r,2} \times \cdots \times C_{r,d} \). Note that \( |M_{r,i}| \leq k^2 \), for each \( i \in [d_r] \).

We fix the weight function \( w_r \) such that it gives distinct weights to all the monomials in the set \( M_{r,i} \), for each \( i \in [d_r] \). We once again mention that fixing of \( w_r \) does not affect the greedy basis constructed in earlier rounds and hence the monomials which were put in the set \( \mathcal{S} \), because \( w_r \) has less precedence than any \( w_{r'}, \) for \( r' < r \).

For each \( \mathcal{C}_{r,i} \), we construct a basis in a greedy manner going from lower weight to higher weight (according to the weight function \( w \)). Let this set of basis coefficients be \( \mathcal{C}'_{r,i} \) and corresponding monomials be \( M'_{r,i} \), for each \( i \in [d_r] \). Let \( \mathcal{C}' := \mathcal{C}'_{r,1} \times \mathcal{C}'_{r,2} \times \cdots \times \mathcal{C}'_{r,d} \) and \( M' := M'_{r,1} \times M'_{r,2} \times \cdots \times M'_{r,d} \). Arguing similar as before we can say that each coefficient in \( C_{r,i} \setminus \mathcal{C}'_{r,i} \) is in the span of strictly smaller weight coefficients (from \( \mathcal{C}'_{r,i} \)) than itself. Hence, the same can be said about any coefficient in the set \( \mathcal{C} \setminus \mathcal{C}' \). So, all the monomials in the set \( M_{r,i} \setminus M'_{r,i} \) can be put into \( \mathcal{S} \). Now, we are left with monomials \( M'_r = M'_{r,1} \times M'_{r,2} \times \cdots \times M'_{r,d} \) for the next round.

**Iteration \( \log d \):** As in each round, the number of terms in the product gets halved, after \( \log d \) rounds we will be left with just one term, i.e. \( M_{\log d} = M'_{\log d-1,2} = M_{\log d,1} \). Now, we will fix the function \( w_{\log d} \) which separates all the monomials in \( M_{\log d,1} \). By arguments similar as above, we will be finally left with at most \( k' \) monomials in \( \mathcal{S} \), which will all have distinct weights. It is clear that for every monomial in \( \mathcal{S} \), its coefficient will be in the span of strictly smaller weight coefficients than itself.

Now, let us look at the cost of this weight function. In the first round, \( w_0 \) needs to separate at most \( O(ds^2) \) many pairs of monomials. For each \( 1 \leq r \leq \log d \), \( w_r \) needs to separate at most \( O(dk^3) \) many pairs of monomials. From Lemma 4, to construct \( w_r \), for any \( 0 \leq r \leq \log d \), one needs to try \( \text{poly}(k,s,n,\delta) \)-many weight functions each having highest weight at most \( \text{poly}(k,s,n,\delta) \) (as \( d \) is bounded by \( n \)). To get the correct combination of the weight functions \( (w_0, w_1, \ldots, w_{\log d}) \) we need to try all possible combinations of these polynomially many choices for each \( w_r \). Thus, we have to try \( (\text{poly}(k,s,n,\delta))^{\log d} \) many combinations.

To combine these weight functions we can choose a large enough number \( B \) (greater than the highest weight a monomial can get in any of the weight functions), and define \( w := w_0 B^{\log d} + w_1 B^{\log d - 1} + \cdots + w_{\log d} \). The choice of \( B \) ensures that the different weight functions cannot interfere with each other, and they also get the desired precedence order.

The highest weight a monomial can get from the weight function \( w \) would be \( (\text{poly}(k,s,n,\delta))^{\log d} \). Thus, the cost of \( w \) remains \( (\text{poly}(k,s,n,\delta))^{\log d} \).

\( \square \)

Combining Lemma 8 with Observation 7 and Lemma 6, we can get a hitting set for ROABP.

**Theorem 1 (restated).** Let \( C(x) \) be an \( n \)-variate polynomial computed by a width-\( w \), \( s \)-sparse-factor ROABP, with individual degree bound \( \delta \). Then there is a \( \text{poly}(w,s,n,\delta)^{\log n} \)-time hitting set for \( C(x) \).

**Proof.** As mentioned earlier, \( C(x) \) can be written as \( R \cdot D(x) \), for some \( R \in M_{w \times w} (\mathbb{F}) \), where \( D(x) \in M_{w \times w} (\mathbb{F})[x] \). The underlying matrix algebra \( M_{w \times w} (\mathbb{F}) \) has dimension \( w^2 \). The hitting set size will be dominated by the cost of the weight function constructed in Lemma 8. As the parameter \( d \) in Lemma 8, i.e. the number of layers in the ROABP, is bounded by \( n \), the hitting set size will be \( \text{poly}(w,s,n,\delta)^{\log n} \). \( \square \)
4. Sum of constantly many set-multilinear circuits: Theorem 2. To find a hitting set for a sum of constantly many set-multilinear circuits, we build some tools. The first is depth-3 multilinear circuits with ‘small distance’. As it turns out, a multilinear polynomial depth computed by a depth-3 \( \Delta \)-distance circuit (top fan-in \( k \)) can also be computed by a width-\( O(kn^\Delta) \) ROABP (Lemma 14). Thus, we get a \( \text{poly}(nk)^{\Delta \log n} \)-time hitting set for this class, from Theorem 1. For our main result (Theorem 2), we only use 1-distance circuits. But we present our results for arbitrary distance circuits, as they are of independent interest and do not follow immediately from those for 1-distance.

Next, we use a general result about finding a hitting set of size \( h^m \) for a class \( m \)-base-sets-\( C \) if a hitting set of size \( h \) is known for class \( C \) (Lemma 17). A polynomial is in \( m \)-base-sets-\( C \) if there exists a partition of the variables into \( m \) base sets such that restricted to each base set (treat other variables as field constants), the polynomial is in class \( C \). Finally, we show that a sum of constantly many set-multilinear circuits falls into the class \( m \)-base-sets-\( \Delta \)-distance, for \( m \Delta = o(n) \). Thus, we get Theorem 2.

4.1. \( \Delta \)-distance circuits. Recall that each product gate in a depth-3 multilinear circuit induces a partition on the variables. Let these partitions be \( \mathbb{P}_1, \mathbb{P}_2, \ldots, \mathbb{P}_k \).

Definition 9 (Distance for a partition sequence). Let \( \mathbb{P}_1, \mathbb{P}_2, \ldots, \mathbb{P}_k \in \text{Part}(\{1\ldots n\}) \) be the \( k \) partitions of the variables \( \{x_1, x_2, \ldots, x_n\} \). Then \( d(\mathbb{P}_1, \mathbb{P}_2, \ldots, \mathbb{P}_k) = \Delta \) if \( \forall i \in \{2, 3, \ldots, k\}, \forall \text{ colors } Y_1 \in \mathbb{P}_i, \exists Y_2, Y_3, \ldots, Y_{\Delta'} \in \mathbb{P}_i (\Delta' \leq \Delta) \) such that \( Y_1 \cup Y_2 \cup \cdots \cup Y_{\Delta'} = \text{ a union of some colors in } \mathbb{P}_j, \forall j \in [i - 1] \).

In other words, in every partition \( \mathbb{P}_i \), each color \( Y_1 \) has a set of colors called ‘friendly neighborhood’, \( \{Y_1, Y_2, \ldots, Y_{\Delta'}\} \), consisting of at most \( \Delta \) colors, which is exactly partitioned in the ‘upper partitions’. We call \( \mathbb{P}_i \), an upper partition relative to \( \mathbb{P}_j \) (and \( \mathbb{P}_j \), a lower partition relative to \( \mathbb{P}_i \), if \( i < j \). For a color \( X_\alpha \) of a partition \( \mathbb{P}_j \), let \( \text{nbhd}_j(X_\alpha) \) denote its friendly neighborhood. For example, for the partitions \( \mathbb{P}_1 = \{(1,2), (3), (5), (6)\} \) and \( \mathbb{P}_2 = \{(1,3), (2,4), (5), (6)\} \), \( d(\mathbb{P}_1, \mathbb{P}_2) = 2 \). In partition \( \mathbb{P}_2 \), the set \( \{(1,3), (2,4)\} \) is a friendly neighborhood and the set \( \{(5), (6)\} \) is another.

The friendly neighborhood \( \text{nbhd}_j(x_i) \) of a variable \( x_i \) in a partition \( \mathbb{P}_j \) is defined as \( \text{nbhd}_j(\text{color}_j(x_i)) \), where \( \text{color}_j(x_i) \) is the color in the partition \( \mathbb{P}_j \) that contains the variable \( x_i \).

Definition 10 (\( \Delta \)-distance circuits). A multilinear depth-3 circuit \( C \) has \( \Delta \)-distance if its product gates can be ordered to correspond to a partition sequence \( (\mathbb{P}_1, \ldots, \mathbb{P}_k) \) with \( d(\mathbb{P}_1, \mathbb{P}_2, \ldots, \mathbb{P}_k) \leq \Delta \).

For example, the circuit \((1+x_1+x_2)(1+x_3)(1+x_4)(1+x_5+x_6)+(1+x_1+x_3)(1+x_2+x_4)(1+x_5)(1+x_6)\) has 2-distance. Every depth-3 multilinear circuit is thus an \( n \)-distance circuit. A circuit with a partition sequence, where the partition \( \mathbb{P}_i \) is a refinement of the partition \( \mathbb{P}_{i+1}, \forall i \in [k-1] \), exactly characterizes a 1-distance circuit. All depth-3 multilinear circuits have distance between 1 and \( n \). Also observe that the circuits with 1-distance strictly subsume set-multilinear circuits. E.g. a circuit, whose product gates induce two different partitions \( \mathbb{P}_1 = \{\{1\}, \{2\}, \ldots, \{n\}\} \) and \( \mathbb{P}_2 = \{\{1,2\}, \{3,4\}, \ldots, \{n-1, n\}\} \), has 1-distance but is not set-multilinear.

Friendly neighborhoods - To get a better picture, we ask: Given a color \( X_\alpha \) of a partition \( \mathbb{P}_j \) in a circuit \( D(x) \), how do we find its friendly neighborhood \( \text{nbhd}_j(X_\alpha) \)? Consider a graph \( G_j \) which has the colors of the partitions \( \mathbb{P}_1, \mathbb{P}_2, \ldots, \mathbb{P}_j \), as its vertices. For all \( i \in [j-1] \), there is an edge between the colors \( X \in \mathbb{P}_i \) and \( Y \in \mathbb{P}_j \) if they share at least one variable. Observe that if any two colors \( X_\alpha \) and \( X_\beta \) of partition \( \mathbb{P}_j \) are reachable from each other in \( G_j \), then, they should be in the same neighborhood.
As reachability is an equivalence relation, the neighborhoods are equivalence classes of colors.

Moreover, observe that for any two variables \(x_a\) and \(x_b\), if their respective colors in partition \(P_j\), color\(_j\)(\(x_a\)) and color\(_j\)(\(x_b\)) are reachable from each other in \(G_j\) then their respective colors in partition \(P_{j+1}\), color\(_{j+1}\)(\(x_a\)) and color\(_{j+1}\)(\(x_b\)) are also reachable from each other in \(G_{j+1}\). Hence, we get the following.

**Observation 11.** If at some partition, the variables \(x_a\) and \(x_b\) are in the same neighborhood, then, they will be in the same neighborhood in all of the lower partitions. I.e. \(nbd_j(x_a) = nbd_j(x_b) \implies nbd_i(x_a) = nbd_i(x_b), \forall i \geq j\).

In other words, if we define a new sequence of partitions, such that the \(j\)-th partition has \(x_a\) and \(x_b\) in the same color if \(nbd_j(x_a) = nbd_j(x_b)\), then the upper partitions are refinements of the lower partitions.

**4.1.1. Reduction to ROABP.** Now, we show that any polynomial computed by a low-distance multilinear depth-3 circuit can also be computed by a small size ROABP. First we make the following observation about sparse polynomials.

**Observation 12.** Any multilinear polynomial \(C(x)\) with sparsity \(s\) can be computed by a width-\(s\) ROABP, in any variable order.

**Proof.** Let \(\mathcal{M}\) denote the set of monomials in \(C\), and let \(C_m\) denote coef\(_C(m)\). Consider an ABP with \(n+1\) layers of vertices \(V_1, V_2, \ldots, V_{n+1}\) each having \(s\) vertices (one for each monomial in \(\mathcal{M}\)) together with a start vertex \(v_0\) and an end vertex \(v_{n+2}\). Let \(v_{i,m}\) denote the \(m\)-th vertex of the layer \(V_i\), for any \(i \in [n+1]\) and any \(m \in \mathcal{M}\).

The edge labels in the ABP are given as follows: For all \(m \in \mathcal{M}\),
- The edge \((v_0, v_{1,m})\) is labelled by \(C_m\),
- The edge \((v_{n+1,m}, v_{n+2})\) is labelled by 1,
- For all \(i \in [n]\), the edge \((v_{i,m}, v_{i+1,m})\) is labelled by \(x_i\) if the monomial \(m\) contains \(x_i\), otherwise by 1.

All other edges get labelled by 0. Clearly, the ABP constructed computes the polynomial \(P(x)\) and it is an ROABP.

Also, note that this construction can be done with any desired variable order. \(\square\)

Now, consider a depth-3 \(\Delta\)-distance multilinear polynomial \(P = \sum_{i=1}^{k} a_i Q_i\), where each \(Q_i = \prod_{j=1}^{m_i} \ell_{ij}\) is a product of linear polynomials. We will construct an ROABP for each \(Q_i\). We can combine these ROABPs to construct a single ROABP if they all have the same variable order. To achieve this we use the refinement property described above (from Observation 11).

**Lemma 13 (Achieving same order).** Let \(P = \sum_{i=1}^{k} a_i Q_i\) be a multilinear polynomial computed by a \(\Delta\)-distance circuit. Then we can make a width-\(O(n^\Delta)\) ROABP for each \(Q_i\), in the same variable order.

**Proof.** Each \(Q_i\) is a product of linear forms in disjoint set of variables, say \(Q_i = \prod_{j=1}^{m_i} \ell_{ij}\). Let the partition induced on the variable set, by the product \(Q_i\), be \(P_i\), for all \(i \in [k]\). Without loss of generality let the partition sequence \((P_1, P_2, \ldots, P_k)\) have distance \(\Delta\). For each \(i \in [k]\), let us define a new partition \(P'_i\), such that the union of colors in each neighborhood of \(P_i\) forms a color of \(P'_i\). This is a valid definition, as neighborhoods are equivalence classes of colors. From Observation 11, the partition \(P'_i\) is a refinement of partition \(P_j\), for any \(i < j\).

For a partition \(P\) of the variable set \(x\), an ordering on its colors \((c_1 < c_2 < \cdots < c_r)\) naturally induces a partial ordering on the variables, i.e. for any \(x_i \in c_j\) and \(x_j \in c_{j'}\), \(c_j < c_{j'} \implies x_i < x_j\). The variables in the same color do not have any relation.

Let us say, a variable (partial) order \(\langle \cdot,\cdot \rangle\) respects a partition \(P\) with colors \(\{c_1, c_2, \ldots, c_r\}\), if there exists an ordering of the colors \((c_{j_1} < c_{j_2} < \cdots < c_{j_r})\),
such that its induced partial order (\(<\)) on the variables can be extended to \(<^*\). We claim that there exists a variable order \((<^*)\) which respects partition \(P'_i\), for all \(i \in [k]\).

We build this variable order \((<^*)\) iteratively. We start with \(P'_1\). We give an arbitrary ordering to the colors in \(P'_1\), say \((c_{k,1} < c_{k,2} < \cdots < c_{k,r_k})\), which induces a partial order \((<_k)\) on the variables. For any \(k > i \geq 1\), let us define a partial order \((<_i)\) inductively as follows: Let \((<_{i+1})\) be a partial order on the variables induced by an ordering on the colors of \(P'_{i+1}\). As mentioned earlier, the colors of \(P'_i\) are just further partitions of the colors of \(P'_{i+1}\). Hence, we can construct an ordering on the colors of \(P'_i\), such that the induced partial order \((<_i)\) is an extension of \((<_{i+1})\). To achieve that, we do the following: For each color \(c \in P'_{i+1}\), fix an arbitrary ordering among those colors of \(P'_i\), whose union forms \(c\).

Clearly, the partial order \((<_1)\) defined in such a way respects \(P'_i\) for all \(i \in [k]\). We further fix an arbitrary ordering among variables belonging to the same color in \(P'_i\). Thus, we get a total order \((<_i)\), which is an extension of \(<_1\) and hence respects \(P'_i\) for all \(i \in [k]\).

Now, we construct an ROABP for each \(Q_i\) in the variable order \(<^*\). First, we multiply out the linear forms which belong to the same neighborhood in each \(Q_i\). That is, we write \(Q_i\) as the product \(\prod_{j=1}^{r_i} Q_{ij}\), where \(r_i\) is the number of neighborhoods in \(P'_i\) (number of colors in \(P'_i\)) and each \(Q_{ij}\) is the product of linear forms (colors) which belong to the same neighborhood in \(P_i\). As, the partition sequence has distance \(\Delta\), the neighborhoods have at most \(\Delta\) colors. So, the degree of each \(Q_{ij}\) is bounded by \(\Delta\) and hence the sparsity is bounded by \(O(n^\Delta)\). By Observation 12, we can construct a width-\(O(n^\Delta)\) ROABP for \(Q_{ij}\) in the variable order given by \(<^*\).

Let \(c_{ij}\) denote the color of \(P'_i\) corresponding to \(Q_{ij}\). As the order \(<^*\) respects \(P'_i\), it gives an order on its colors, say \(c_{ij_1} < c_{ij_2} < \cdots < c_{ij_{r_i}}\). Now, we arrange the ROABPs for \(Q_{ij}\)'s in the order \(Q_{ij_1}, Q_{ij_2} \ldots Q_{ij_{r_i}}\), while identifying the end vertex of \(Q_{ij_a}\), with the start vertex of \(Q_{ij_{a+1}}\), for all \(a \in [r_i - 1]\). Clearly the ROABP thus constructed computes the polynomial \(Q_i\) and has variable order \(<^*\).

Once we have ROABPs for the polynomials \(Q_i\)'s in the same variable order, let us make a new start node and connect it with the start node of the ROABP for \(Q_i\) with label \(a_i\), for all \(i \in [k]\). Also, let us make a new end node and connect it with the end node of the ROABP for \(Q_i\) with label 1, for all \(i \in [k]\). Clearly, the ROABP thus constructed computes the polynomial \(P = \sum_{i=1}^{k} a_i Q_i\) and has width \(O(kn^\Delta)\). Thus, we can write

**Lemma 14 (\(\Delta\)-distance to ROABP).** An \(n\)-variate multilinear polynomial computed by a depth-3, \(\Delta\)-distance circuit with top fan-in \(k\) has a width-\(O(kn^\Delta)\) ROABP.

Hence, from Theorem 1 we get,

**Theorem 15 (\(\Delta\)-distance Hitting Set).** Let \(C(x)\) be a depth-3, \(\Delta\)-distance, \(n\)-variate multilinear circuit with top fan-in \(k\). Then there is a \((nk)^{O(\Delta \log n)}\)-time hitting-set for \(C(x)\).

### 4.2. Base sets with \(\Delta\)-distance.

In this section we describe our second tool towards finding a hitting set for sum of constantly many set-multilinear polynomials. We further generalize the class of polynomials, for which we can give an efficient test, beyond low-distance. Basically, it is enough to have low-distance “projections”.

**Definition 16.** A multilinear depth-3 circuit \(C(x)\) is said to have \(m\)-base-sets-\(\Delta\)-distance if there is a partition of the variable set \(x\) into base sets \(\{x_1, x_2, \ldots, x_m\}\) such that for any \(i \in [m]\), restriction of \(C\) on the \(i\)-th base set (i.e. other variables are considered as function field constants), has \(\Delta\)-distance.
For example, the circuit \((1 + x_1 + y_1)(1 + x_2 + y_2) \cdots (1 + x_n + y_n) + (1 + x_1 + y_2)(1 + x_2 + y_3) \cdots (1 + x_n + y_1)\) has \(n\)-distance, but when restricted to either base set \(\{x_i\}\), or base set \(\{y_i\}\), it has 1-distance. Thus, it has 2-base-sets-1-distance. We will show that there is an efficient hitting set for this class of polynomials. In fact, we can show a general easy result for a polynomial whose restriction on one base set falls into a class \(C\), for which a hitting set is already known. Here, by \(F\) we mean the algebraic closure of \(F\). Actually a sufficiently large field extension of \(F\) suffices for the proof.

**Lemma 17 (Hybrid Argument).** Let \(H\) be the hitting set for a class \(C\) of \(n\)-variate polynomials over field \(F\). Let \(x\) be a union of \(m\) disjoint sets of variables \(x_1 \sqcup x_2 \sqcup \cdots \sqcup x_m\), called base sets, each with size at most \(n\). Let \(C(x)\) be a polynomial such that for all \(i \in [m]\), its restriction to the base set \(x_i\) is in class \(C\), i.e. for all points \((a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_m) \in \mathbb{F}^n\), the polynomial \(C(x_1 = a_1, \ldots, x_i = a_i, x_{i+1} = a_{i+1}, \ldots, x_m = a_m))\) is in class \(C\). Then there is a hitting set for \(C(x)\) of size \(|H|^m\) (with the knowledge of the base sets).

**Proof.** Let us assume that the set \(x_i\) has cardinality \(n\), for all \(i \in [m]\). If not, then we can introduce dummy variables. Now, we claim that if \(C(x) \neq 0\) then there exists \(m\) points \(h_1, h_2, \ldots, h_m \in H\), such that \(C(x_1 = h_1, x_2 = h_2, x_m = h_m) \neq 0\).

We prove the claim inductively.

**Base Case:** The polynomial \(C(x_1, x_2, \ldots, x_m) \neq 0\). It follows from the assumption.

**Induction Hypothesis:** There exist points \(h_1, h_2, \ldots, h_i \in H\) such that the partially evaluated polynomial \(C'(x_{i+1}, \ldots, x_m) := C(x_1 = h_1, \ldots, x_i = h_i, x_{i+1}, \ldots, x_m) \neq 0\).

**Induction Step:** We show that there exists \(h_{i+1} \in H\) such that the polynomial \(C''(x_{i+1} = h_{i+1}, x_{i+2}, \ldots, x_m) \neq 0\).

As the polynomial \(C'(x_{i+1}, \ldots, x_m)\) is nonzero, there exist points \(a_{i+2}, \ldots, a_m \in \mathbb{F}^n\) such that \(C''(x_{i+1} = a_{i+2}, \ldots, x_m = a_m) \neq 0\) (from Schwartz-Zippel Lemma, see [SY10, Fact 4.1]). We know that \(C''(x_{i+1})\) is in class \(C\). So, there must exist a point \(h_{i+1} \in H\) such that \(C''(x_{i+1} = h_{i+1}) \neq 0\). This clearly implies that \(C''(x_{i+1} = h_{i+1}, x_{i+2}, \ldots, x_m) \neq 0\). Thus, the claim is true.

Now, to construct a hitting set for \(C\), one needs to substitute the set \(H\) for each base set \(x_i\), i.e. the Cartesian product \(H \times \cdots \times H\) (\(m\) times). Hence, we get a hitting set of size \(|H|^m\).

\[\square\]

Note that, in the above proof the knowledge of the base sets is crucial. This lemma, together with Theorem 15, gives us the following:

**Theorem 18 (\(m\)-base-sets-\(\Delta\)-distance PIT).** If \(C(x)\) is a depth-3 multilinear circuit, with top fan-in \(k\), having \(m\)-base-sets (known) with \(\Delta\)-distance, then there is a \((nk)^{O(m\Delta \log n)}\)-time hitting set for \(C\).

### 4.3. Sum of set-multilinear circuits reduces to \(m\)-base-sets-\(\Delta\)-distance.

In this section, we will reduce the PIT for sum of constantly many set-multilinear depth-3 circuits, to the PIT for depth-3 circuits with \(m\)-base-sets-\(\Delta\)-distance, where \(m\Delta = o(n)\). Thus, we get a subexponential time whitebox algorithm for this class (from Theorem 18). Note that a sum of constantly many set-multilinear depth-3 circuits is equivalent to a depth-3 multilinear circuit such that the number of distinct partitions, induced by its product gates, is constant.

We first look at the case of two partitions. For a partition \(P\) of \([n]\), let \(P|_B\) denote the restriction of \(P\) on a base set \(B \subseteq [n]\). E.g., if \(P = \{\{1, 2\}, \{3, 4\}, \{5, 6, \ldots, n\}\}\) and
$B = \{1, 3, 4\}$ then $|B| = \{\{1\}, \{3, 4\}\}$. Recall that $d(B_1, B_2, \ldots, B_c)$ denotes the distance of the partition sequence $(B_1, B_2, \ldots, B_c)$ (Definition 9). For a partition sequence $(B_1, B_2, \ldots, B_c)$, and a base set $B \subseteq [n]$, let $d_B(B_1, B_2, \ldots, B_c)$ denote the distance of the partition sequence when restricted to the base set $B$, i.e. $d(B_1, B_2, \ldots, B_c)$.

**Lemma 19 (c = 2).** For any two partitions $\{P_1, P_2\}$ of the set $[n]$, there exists a partition of $[n]$, into at most $2\sqrt{n}$ base sets $\{B_1, B_2, \ldots, B_m\}$ ($m < 2\sqrt{n}$), such that for any $i \in [m]$, either $d_B(P_1, P_2) = 1$ or $d_B(P_2, P_1) = 1$.

**Proof.** Let us divide the set of colors in the partition $P_1$, into two types of colors: One with at least $\sqrt{n}$ elements and the other with less than $\sqrt{n}$ elements. In other words, $P_1 = \{X_1, X_2, \ldots, X_r\} \cup \{Y_1, Y_2, \ldots, Y_g\}$ such that $|X_i| \geq \sqrt{n}$ and $|Y_j| < \sqrt{n}$, for all $i \in [r]$, $j \in [g]$. Let us make each $X_i$ a base set, i.e. $B_i = X_i$, $\forall i \in [r]$. As $|X_i| \geq \sqrt{n}$, $\forall i \in [r]$, we get $r \leq \sqrt{n}$. Now, for any $i \in [r]$, $P_1|_{B_i}$ has only one color. Hence, irrespective of what colors $P_2|_{B_i}$ has, $d_B(P_2, P_1) = 1$, for all $i \in [r]$.

Now, for the other kind of colors, we will make base sets which have exactly one element from each color $Y_j$. More formally, let $Y_j = \{y_{j,1}, y_{j,2}, \ldots, y_{j,r_j}\}$, for all $j \in [g]$. Let $r' = \max\{r_1, r_2, \ldots, r_g\}$ ($r' < \sqrt{n}$). Now define base sets $B'_1, B'_2, \ldots, B'_a$, such that for any $a \in [r']$, $B'_a = \{y_{j, a} \mid j \in [g], |Y_j| \geq a\}$. In other words, all those $Y_j$s which have at least $a$ elements, contribute their $a$-th element to $B'_a$. Now for any $a \in [r']$, $P_1|_{B'_a} = \{\{y_{j,a}\} \mid j \in [g], |Y_j| \geq a\}$, i.e. it has exactly one element in each color. Clearly, irrespective of what colors $P_2|_{B'_a}$ has, $d_B(P_2, P_1) = 1$, for all $a \in [r']$. $\{B_1, B_2, \ldots, B_r\} \cup \{B'_1, B'_2, \ldots, B'_a\}$ is our final set of base sets. Clearly, they form a partition of $[n]$. The total number of base sets, $m = r + r' < 2\sqrt{n}$.

Now, we generalize Lemma 19 to any constant number of partitions, by induction.

**Lemma 20 (Reduction to m-base-sets-1-distance).** For any set of $c$ partitions $\{P_1, P_2, \ldots, P_c\} \subseteq \text{Part}([n])$, there exists a partition of the set $[n]$, into $m$ base sets $\{B_1, B_2, \ldots, B_m\}$ with $m < (4n)^{1-(1/2^{c-1})}$ such that for any $i \in [m]$, there exists a permutation of the partitions, $(P_{i_1}, P_{i_2}, \ldots, P_{i_m})$ with $d_{B_i}(P_{i_1}, P_{i_2}) = 1$.

**Proof.** Let $f(c, n) := (4n)^{1-(1/2^{c-1})}$. The proof is by induction on the number of partitions.

**Base case:** For $c = 2$, $f(c, n)$ becomes $2\sqrt{n}$. Hence, the statement follows from Lemma 19.

**Induction hypothesis:** The statement is true for any $c - 1$ partitions.

**Induction step:** Like in Lemma 19, we divide the set of colors in $P_1$ into two types of colors. Let $P_1 = \{X_1, X_2, \ldots, X_r\} \cup \{Y_1, Y_2, \ldots, Y_g\}$ such that $|X_i| \geq \sqrt{n}$ and $|Y_j| < \sqrt{n}$, for all $i \in [r]$, $j \in [g]$. Let us make each $X_i$ a base set, and let $n_i := |B_i|$, for all $i \in [r]$. Our base sets will be further subsets of these $B_i$s. For a fixed $i \in [r]$, let us define $P'_h = P_h|_{B_i}$, as a partition of the set $B_i$, for all $h \in [c]$. Clearly, $P'_h$ has only one color. Now, we focus on the partition sequence $(P'_2, P'_3, \ldots, P'_c)$. From the inductive hypothesis, there exists a partition of $B_i$ into $m_i$ base sets $\{B_{i,1}, B_{i,2}, \ldots, B_{i,m_i}\}$ ($m_i < f(c-1, n_i)$) such that for any $a \in [m_i]$, there exists a permutation of $(P'_2, P'_3, \ldots, P'_c)$, given by $(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c})$, with $d_{B_{i,a}}(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c}) = 1$ as $P'_{i,a}$ has only one color, so does $P_{i,a}(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c}, P'_1)$ is also 1. From this, we easily get $d_{B_{i,a}}(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c}, P'_1) = 1$. The above argument can be made for all $i \in [r]$.

Now for the other colors, we proceed as in Lemma 19. Let $Y_j = \{y_{j,1}, y_{j,2}, \ldots, y_{j,r_j}\}$, for all $j \in [g]$. Let $r' = \max\{r_1, r_2, \ldots, r_c\}$ ($r' < \sqrt{n}$). Now define sets $B'_1, B'_2, \ldots, B'_a$, such that for any $a \in [r']$, $B'_a = \{y_{j,a} \mid j \in [g], |Y_j| \geq a\}$. In other words, all those $Y_j$s which have at least $a$ elements, contribute their $a$-th element to $B'_a$. Let $n'_a := |B'_a|$, for all $a \in [r']$. Our base sets will be further subsets of these $B'_a$s. For a fixed $a \in [r']$,
let us define $P'_h = \mathbb{P}|_{B'_h}$, as a partition of the set $B'_h$, for all $h \in [c]$. Clearly, $P'_h$ has exactly one element in each of its colors. Now, we focus on the partition sequence $(P'_2, P'_3, \ldots, P'_{c})$. From the inductive hypothesis, there exists a partition of $B'_a$ into $m'_a$ base sets $\{B'_{a,1}, B'_{a,2}, \ldots, B'_{a,m'_a}\}$ such that for any $u \in [m'_a]$, there exists a permutation of $(P'_{2}, P'_{3}, \ldots, P'_{c})$, given by $(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c})$, with $d_{B'_{a,u}}(P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c}) = 1$. As $P'_h$ has exactly one element in each of its colors, so does $P'_h|_{B'_{a,u}}$. Hence, $d_{B'_{a,u}}(P'_1, P'_{u}, P'_{i_3}, \ldots, P'_{i_c})$ is also 1. From this, we easily get $d_{B'_{a,u}}(P'_1, P'_{i_2}, P'_{i_3}, \ldots, P'_{i_c}) = 1$. The above argument can be made for all $a \in [r']$.

Our final set of base sets will be $\{B_{i,u} \mid i \in [r], u \in [m_i]\} \cup \{B'_{a,u} \mid a \in [r'], u \in [m'_a]\}$. As argued above, when restricted to any of these base sets, the given partitions have a sequence, which has distance 1. Now, we need to bound the number of these base sets,

$$m = \sum_{i \in [r]} m_i + \sum_{a \in [r']} m'_a.$$ 

From the bounds on $m_i$ and $m'_a$, we get

$$m < \sum_{i \in [r]} f(c - 1, n_i) + \sum_{a \in [r']} f(c - 1, n'_a).$$

Recall that $n_i \geq \sqrt{n} \forall i \in [r]$ and $\sum_{i \in [r]} n_i \leq n$, thus $r < \sqrt{n}$. Also, we know that $r' < \sqrt{n}$. Let us combine the two sums by defining $n_{i+a} := n'_a$ for all $a \in [r']$ and $r'' := r + r'$.

$$m < \sum_{i \in [r'']} f(c - 1, n_i).$$

We know that $r'' < 2\sqrt{n}$ and $\sum_{i \in [r'']} n_i = n$. Observe that $f(c - 1, z)$, as a function of $z$, is a concave function (its derivative is monotonically decreasing, when $z > 0$). From the properties of a concave function, we know,

$$\frac{1}{r''} \sum_{i \in [r'']} f(c - 1, n_i) \leq f\left(c - 1, \frac{1}{r''} \sum_{i \in [r'']} n_i\right) = f(c - 1, n/r'').$$

Equivalently,

$$\sum_{i \in [r'']} f(c - 1, n_i) \leq r''(4n/r'')^{1-(1/2^{c-2})}$$

$$= (4n)^{1-(1/2^{c-2})} \cdot (r'')^{1/2^{c-2}}$$

$$< (4n)^{1-(1/2^{c-2})} \cdot (4n)^{1/2^{c-1}} \quad (: r'' < \sqrt{4n})$$

$$= (4n)^{1-(1/2^{c-1})}.$$ 

Thus we get,

$$m < (4n)^{1-(1/2^{c-1})}.$$
Now, we combine these results with our hitting-sets for depth-3 circuits having $m$-base-sets with $\Delta$-distance.

**Theorem 2 (restated).** Let $C(x)$ be a $n$-variate polynomial, which can be computed by a sum of $c$ set-multilinear depth-3 circuits, each having top fan-in $k$. Then there is a $(nk)^{O(n^{1-\log n})}$-time whitebox PIT test for $C$, where $\epsilon := 1/2^{\omega(n)}$.

**Proof.** As mentioned earlier, the polynomial $C(x)$ can be viewed as being computed by a depth-3 multilinear circuit, such that its product gates induce at most $c$ distinct partitions. From Lemma 20, we can partition the variable set into $m$ base sets, such that for each of these base sets, the partitions can be sequenced to have distance 1, where $m < (4n)^{1-\epsilon}$. Hence, the polynomial $C$ has $m$-base-sets with 1-distance and top fan-in $ck$. Moreover, from the proof of Lemma 20, it is clear that such base sets can be computed in $n^{O(\epsilon)}$-time. From Theorem 18, we know that there is $(nk)^{O(m \log n)}$-time whitebox PIT test for such a circuit. As $m = O(n^{1-\epsilon})$, we get the result. \(\square\)

**Tightness of this method for $c = 2$.** Lemma 19 can be put in other words as: Any two partitions have $m$-base-sets-$\Delta$-distance with $m\Delta = O(\sqrt{n})$. We can, in fact, show that this result is tight.

**Showing the lower bound:** Let $d(P_1, P_2) = \Delta$. Then each color of $P_2$ has a friendly neighborhood (of at most $\Delta$ colors) which is exactly partitioned in $P_1$. Now construct $\Delta$ base sets such that $i$-th base set takes the variables of $i$-th color from every neighborhood of $P_2$. Clearly, when restricted to one of these bases sets, $d(P_1, P_2)$ is 1. In other words $P_1$ and $P_2$ have $\Delta$-base-sets-1-distance. Similarly, one can argue that if $P_1$ and $P_2$ have $m$-base-sets-$\Delta$-distance then they also have $m\Delta$-base-sets-1-distance. Now, we will show that if we want $m$-base-sets-1-distance for two partitions then $m = \Omega(\sqrt{n})$.

Consider the following example (assuming $n$ is a square):

$P_1 = \{\{1, 2, \ldots, \sqrt{n}\}, \{\sqrt{n} + 1, \sqrt{n} + 2, \ldots, 2\sqrt{n}\}, \ldots, \{\sqrt{n}(\sqrt{n} - 1) + 1, \sqrt{n}(\sqrt{n} - 1) + 2, \ldots, n\}\}$

$P_2 = \{\{1, \sqrt{n} + 1, \ldots, n - \sqrt{n} + 1\}, \{2, \sqrt{n} + 2, \ldots, n - \sqrt{n} + 2\}, \ldots, \{\sqrt{n}, 2\sqrt{n}, \ldots, n\}\}$.

Basically, $P_2$ has the residue classes (mod $\sqrt{n}$).

**Observation 21.** A base set $B$, such that $d_B(P_1, P_2) = 1$, has at most $\sqrt{n}$ variables.

**Proof.** Suppose it has more than $\sqrt{n}$ variables. Then, there is at least one color in $P_1$ which contributes two variables to $B$. These two variables have to be in two different colors of $P_2$ (because of our design of $P_1$ and $P_2$). So, $d_B(P_1, P_2)$ is at least 2. We get a contradiction. \(\square\)

The number of such base sets has to be at least $\sqrt{n}$. Combining this with the reduction from $m$-base-sets-$\Delta$-distance to $m\Delta$-base-sets-1-distance, we get $m\Delta = \Omega(\sqrt{n})$.

It is not clear if Lemma 20 is tight. We conjecture that for any set of partitions, $m\Delta = O(\sqrt{n})$ can be achieved.

**5. Sparse-Invertible Width-$w$ ROABP: Theorem 3.** As mentioned in the Preliminaries (Section 2), a polynomial $C(x)$ computed by a $s$-sparse-factor width-$w$ ROABP can be written as $D_0(D_1(D_2 \ldots D_d)_{d+1})$, where $D_0, D_{d+1} \in \mathbb{F}_w$, $D_i \in \mathbb{F}_w^{w \times w}$, $x_i$ are disjoint sets of variables.

We will show a hitting-set for a sparse-factor ROABP $D_0(\prod_{i=1}^d D_i)_{d+1}$, where the $D_i$s are invertible matrices, for all $i \in [d]$. Hence, we name this model sparse-
invertible-factor ROABP.

For a polynomial $D$, let its sparsity $s(D)$ be the number of monomials in $D$ with nonzero coefficients.

**Theorem 3** (restated). Let $x = x_1 \sqcup \cdots \sqcup x_d$, with $|x| = n$. Let $C(x) = D_0^T DD_{d+1} \in \mathbb{F}[x]$ be a polynomial with $D_0, D_{d+1} \in \mathbb{F}^{w}$, $D(x) = \prod_{i=1}^{d} D_i(x)$, and for all $i \in [d]$, $D_i \in \mathbb{F}^{w \times w}[x_i]$ is an invertible matrix. For all $i \in [d]$, $D_i$ has degree bounded by $\delta$ and sparsity $s(D_i) \leq s$. Then there is a hitting-set of size poly($(n\delta s)^w \log w$) for $C(x)$.

**Remark 1**. If the width $w$ is constant, then it is clear that we get a polynomial sized hitting-set.

**Remark 2**. If the $D_i$s are univariate, then we get a $(n\delta)^{O(w^2)}$ sized hitting-set. The proof is presented along with the proof of Theorem 3.

Like [ASS13] and [FSS14], we find a hitting-set by showing a low-support concentration. Low-support concentration in the polynomial $D(x) = \prod_{i=1}^{d} D_i$ means that the coefficients of the low-support monomials in $D(x)$ span the whole coefficient space of $D(x)$.

Let $x$ be $\{x_1, x_2, \ldots, x_n\}$. For an exponent $e = (e_1, e_2, \ldots, e_m) \in \mathbb{Z}_+^n$, and for a set of variables $y = \{y_1, y_2, \ldots, y_m\}$, $y^e$ will denote $y_1^{e_1} y_2^{e_2} \cdots y_m^{e_m}$. For any $e \in \mathbb{Z}_+^n$, support of the monomial $x^e$ is defined as $S(e) := \{i \in [n] \mid e_i \neq 0\}$ and support size is defined as $s(e) := |S(e)|$. Now, we define $\ell$-concentration for a polynomial $D(x) \in \mathbb{F}^{w \times w}[x]$.

**Definition 22** ($\ell$-concentration). A polynomial $D(x) \in \mathbb{F}^{w \times w}[x]$ is $\ell$-concentrated if $\text{rank}_F(\text{coef}_D(x^e) \mid e \in \mathbb{Z}_+^n, s(e) < \ell) = \text{rank}_F(\text{coef}_D(x^e) \mid e \in \mathbb{Z}_+^n)$.

We will later see that the low-support concentration in polynomial $D(x)$ implies low-support concentration in polynomial $C(x)$ (defined similarly). In other words, $C(x)$ will have a nonzero coefficient for at least one of the low-support monomials. Thus, we get a hitting set by testing these low-support coefficients. We use the following Lemma from [ASS13].

**Lemma 23**. If $C(x) \in \mathbb{F}[x]$ is an $n$-variate, $\ell$-concentrated polynomial with highest individual degree $\delta$, then there is a $(n\delta)^{O(\ell)}$-time hitting-set for $C(x)$.

**Proof**. $\ell$-concentration for $C(x)$ simply means that it has at least one ($< \ell$)-support monomial with nonzero coefficient. We will construct a hitting set which essentially will test all these ($< \ell$)-support coefficients. We go over all subsets $S$ of $x$ with size $\ell - 1$ and do the following: Substitute 0 for all the variables outside the set $S$. There will be at least one choice of $S$, for which the polynomial $C(x)$ remains nonzero after the substitution. Now, it is an $(\ell - 1)$-variate nonzero polynomial. We take the usual hitting set $\mathcal{H}^{\ell-1}$ for this, where $\mathcal{H} \subseteq \mathbb{F}$ is a set of size $\delta + 1$ (see, for example, [SY10, Fact 4.1]). In other words, each of these $\ell - 1$ variables are assigned values from the set $\mathcal{H}$.

The number of sets $S$ we need to try are $\binom{n}{\ell - 1}$. Hence, the overall hitting set size is $(n\delta)^{O(\ell)}$. 

It is known that low-support concentration in $D(x)$ gives low-support concentration in $C(x)$ (Lemma 33). Now, we move on to show how to achieve low-support concentration in $D(x) = \prod_{i=1}^{d} D_i$. To achieve that we will use some efficient shift. By shifting by a tuple $\alpha := (\alpha_1, \alpha_2, \ldots, \alpha_n)$, we mean replacement of $x_i$ with $x_i + \alpha_i$. Note that $C(x + \alpha) \neq 0$ if and only if $C(x) \neq 0$. Hence, a hitting set for $C(x + \alpha)$ gives us a hitting set for $C(x)$. Instead of constants, we will shift $C(x)$ by univariate polynomials, say, given by the map $\phi: t \to \{t^a\}_{a \geq 0}$, where $t := \{t_1, t_2, \ldots, t_n\}$. The $\phi$ is said to be an efficient map if $\phi(t_i)$ is efficiently computable, for each $i \in [n]$. 

**Block-Support.** Let the matrix product $D(x) := \prod_{i=1}^{d} D_i$ correspond to an ROABP such that $D_i \in \mathbb{F}^{w \times w}[x_i]$ for all $i \in [d]$. Let $n_i$ be the cardinality of $x_i$ and let $n = \sum_{i=1}^{d} n_i$. Viewing $D_i$ as belonging to $\mathbb{F}^{w \times w}[x_i]$, one can write $D_i := \sum_{e \in \mathbb{Z}_+^n} D_{ie} x_i^e$, where $D_{ie} \in \mathbb{F}^{w \times w}$, for all $e \in \mathbb{Z}_+^n$. In particular $D_{i0}$ refers to the constant part of the polynomial $D_i$.

Any monomial $x^e$ for $e \in \mathbb{Z}_+^n$, can be seen as a product $\prod_{i=1}^{d} x_i^{e_i}$, where $e_i \in \mathbb{Z}_+^{n_i}$ for all $i \in [d]$, such that $e = (e_1, e_2, \ldots, e_d)$. We define block-support of $e$, $bS(e)$ as \{ $i \in [d] | e_i \neq 0$\} and block-support size of $e$, $bs(e) = |bS(e)|$. Thus, the block-support of a monomial is the set of blocks which contribute non-trivially to the monomial.

The coefficient of the monomial $x^e$ is $D_e := \prod_{i=1}^{d} D_{ie}$. Observe that when $i \notin bS(e)$, the $i$-th block contributes its constant part, $D_{i0}$ to the coefficient. The coefficient $D_f$ is called a substring of the coefficient $D_e$ if $bs(f) < bs(e)$ and $f_i = e_i$ whenever $f_i \neq 0$. We will use the operator substrings($e$) to denote the set \{ $f \mid D_f$ is a substring of $D_e$ \}.

Consider the toy example $D = (A_1 + B_{11} x_1 + B_{12} x_1^2)(A_2 + B_{22} x_2)(A_3 + B_{33} x_3 + B_{34} x_3 x_4)$. Here, $D_{i0} = A_i$, for all $i$ and the block-support of the monomial $x_1 x_3 x_4$ is $\{1, 3\}$. $A_1 B_2 B_3$ is a substring of $B_{12} B_2 B_3$, whereas $B_{11} B_2 B_3$ is not.

A substring $D_f$ of $D_e$ is called its prefix if $\forall i \ (f_i \neq e_i \implies (\forall j \geq i, f_j = 0))$. In the above example, it means that only the trailing $B$s can be replaced with the corresponding $A$s. Thus, $B_{12} A_2 A_3$ is a prefix of $B_{12} B_2 B_4$, whereas $B_{12} A_2 B_4$ is not, though both are its substrings. Observe that when the $D_{i0}$s are invertible, if $D_f$ is a prefix of $D_e$, then we can write $D_e = D_f A^{-1} B$, where $A := \prod_{i=r+1}^{d} D_{i0}$ and $B := \prod_{i=r+1}^{d} D_{ie}$, with $r = \max bs(f)$. We will denote the product $A^{-1} B$ as $D_{f^{-1} e}$.

**Proof Idea**

Let $\ell = w^2$ and $\ell^\prime = \log w^2 + 1$. There are four steps that we take to prove low-support concentration in the sparse, invertible-factor, width-$w$ ROABP $D$.

1. Given an invertible matrix $D_i \in \mathbb{F}^{w \times w}[x_i]$, we use a shift, so that the constant part of the shifted matrix is invertible.
2. Assuming the constant part of the shifted matrix $D$ is invertible, we show that any coefficient with block support ($= \ell$) is linearly dependent on its substrings with ($< \ell$) block support (Lemma 25).
3. We use this Lemma to show that any coefficient in $D$ is linearly dependent on its substrings with ($< \ell$) block support (Lemma 26).
4. We show that the shifted polynomial has $\ell^\prime$-concentration within each of the blocks.

The contribution/novel part of this section is in the second step. The remaining steps were already known.

We will give the proof idea for the second step through a toy example. Consider $D = (A_1 + B_{11} x_1)(A_2 + B_{22} x_2) \cdots (A_n + B_{nn} x_n)$, where each of the $A_i$s are invertible and $A_i, B_i \in \mathbb{F}^{w \times w}$, $\forall i$. Take the $\ell$-block-support monomial $x_{[\ell]} := x_1 x_2 \cdots x_\ell$. We will show that its coefficient is linearly dependent on its substrings with ($< \ell$) block-support. Let $M_j = \prod_{i=1}^{j} B_i \prod_{i=j+1}^{d} A_i$, for $0 \leq j \leq \ell$. Consider the set of matrices $\{ M_{j} \}_{j=0}^{\ell}$. These $\ell + 1$ matrices lie in $\mathbb{F}^{\ell}$. Hence, there exists a $r \in [\ell]$ such that $M_r = \sum_{j=0}^{r-1} \alpha_j M_j$, where $\alpha_j \in \mathbb{F}$. All the $M_j$s on the right hand side have $< r$ many $B$s. Since the $A_i$s are invertible, we can post-multiply throughout by $(\prod_{i=r+1}^{d} A_i)^{-1} \prod_{i=r+1}^{d} B_i \prod_{i=\ell+1}^{n} A_i$ to obtain that the coefficient of $x_{[\ell]}$ is linearly dependent on strictly smaller block-support coefficients.

The third step is a simple extension of the above idea. For the first and fourth
steps, we use an appropriate shift (Section 5.1). The sparsity of \( D_i \) is used crucially here.

Note that we have to assume that \( D_i(x_i) \) is an invertible matrix for all \( i \in [d] \).
For the shifted polynomial \( D'_i(x_i) := D_i(x_i + \phi(t_i)) \), its constant term \( D'_{i0} \) is just an evaluation of \( D_i(x_i) \), i.e., \( D_i|_{x_i=\phi(t_i)} \). Hence, if \( \det(D_i(x_i)) = 0 \) (viewing \( D_i(x_i) \) as an element in \( \mathbb{F}[x_i]^{w \times w} \)), then \( \det(D'_{i0}) = 0 \). This means that if \( \det(D_i(x_i)) = 0 \), then even after shifting, \( D'_{i0} \) cannot become invertible.

Let us now prove that a particular kind of dependency can be lifted.

**Lemma 24.** Let \( D_e \) be a prefix of \( D_{e^*} \). If \( D_e \) is linearly dependent on its substrings, then \( D_{e^*} \) is linearly dependent on its substrings.

**Proof.** Since \( D_e \) is a prefix of \( D_{e^*} \),

\[
D_{e^*} = D_e D_{e^{-1}e^*}. \tag{3}
\]

Let the dependence of \( D_e \) on its substrings be the following:

\[
D_e = \sum_{f \in \text{substrings}(e)} \alpha_f D_f.
\]

Using Equation (3) we can write,

\[
D_{e^*} = \sum_{f \in \text{substrings}(e)} \alpha_f D_f D_{e^{-1}e^*}.
\]

Now, we just need to show that for any substring \( D_f \) of \( D_e \), \( D_f D_{e^{-1}e^*} \) is a valid coefficient of some monomial in \( D(x) \) and also that it is a substring of \( D_{e^*} \).

Let \( r = \max\{bs(e)\} \). Recall that \( D_{e^{-1}e^*} = A^{-1}B \), where \( A := \prod_{i=r+1}^{d} D_{i0} \) and \( B := \prod_{i=r+1}^{d} D_{i e^*} \). Thus, \( D_f D_{e^{-1}e^*} \) is the coefficient of \( x^{\ell'} := \prod_{i=r}^{r'} x_i^{e_i} \), \( \prod_{i=r+1}^{d} x_i^{e_i} \).

Since \( f \in \text{substrings}(e) \) and \( e \in \text{substrings}(e^*) \), \( f \in \text{substrings}(e^*) \). From these two facts, it is easy to see that \( D_f D_{e^{-1}e^*} \) is a substring of \( D_{e^*} \).

We will now prove the existence of a dependency for any \( \ell \)-block-support coefficient.

**Lemma 25.** Let \( D_e \) be a coefficient in \( D \) with \( bs(e) = \ell \). Then \( D_e \) \( \mathbb{F} \)-linearly depends on its substrings.

**Proof.** Consider the set of coefficients \( \{ M_0, M_1, \ldots, M_{\ell} \} \), where \( M_j \) is the prefix of \( D_e \) with block support size \( j \), for \( 0 \leq j < \ell \). And \( M_{\ell} = D_e \). These \( \ell + 1 \) vectors lie in \( \mathbb{F}^\ell \cong \mathbb{F}^{w \times w} \). Hence, there exists an \( r \in [\ell] \) such that \( M_r \) is linearly dependent on \( \{ M_j \}_{j=0}^{r-1} \). (Note that \( M_r = 0 \) is also a dependency. Also note that \( r > 0 \), since \( M_0 \) is invertible.) The coefficients in the set \( \{ M_j \}_{j=0}^{r-1} \) are prefixes of \( M_r \), and thus, substrings of \( M_r \).

Now, by applying Lemma 24, we conclude that \( D_e \) is dependent on its substrings.

We will now prove that any coefficient in \( D(x) \) is dependent on coefficients in \( D \) with block-support \( \leq \ell - 1 \). We call this as \( \ell \)-block-concentration in \( D(x) \).

**Lemma 26** (\( \ell \)-Block-concentration). Let \( D(x) = \prod_{i=1}^{d} D_i(x_i) \in \mathbb{F}^{w \times w}[x] \) be a polynomial with \( D_{i0} \) being invertible for each \( i \in [d] \). Then \( D(x) \) has \( \ell \)-block-concentration.

**Proof.** We will actually prove that for any coefficient \( D_e \) with \( bs(e) \geq \ell \) (the case when \( bs(e) < \ell \) is trivial),

\[
D_e \in \text{span}\{ D_f \mid f \in \mathbb{Z}_+^w, f \in \text{substrings}(e) \text{ and } bs(f) \leq \ell - 1\}.
\]
We will prove this by induction on the block-support of $D_e$, $\text{bs}(e)$.

Base case: When $\text{bs}(e) = \ell$, it has been already shown in Lemma 25.

**Induction Hypothesis:** For any coefficient $D_e$ with $\text{bs}(e) = i - 1$ for $i - 1 \geq \ell$,

$D_e \in \text{span}\{D_f \mid f \in \mathbb{Z}^n, f \in \text{substrings}(e) \text{ and } \text{bs}(f) \leq i - 1\}$.

**Induction step:** Let us take a coefficient $D_e$ with $\text{bs}(e) = i$. Consider the unique prefix $D_{e'}$ of $D_e$ such that $\text{bs}(e') = i - 1$.

As $\text{bs}(e') = i - 1$, by our induction hypothesis, $D_{e'}$ is linearly dependent on its substrings. So, from Lemma 24, $D_e$ is linearly dependent on its substrings. In other words,

$$D_e \in \text{span}\{D_f \mid f \in \text{substrings}(e) \text{ and } \text{bs}(f) \leq i - 1\}. \quad (4)$$

Again, by our induction hypothesis, for any coefficient $D_f$, with $\text{bs}(f) \leq i - 1$,

$$D_f \in \text{span}\{D_g \mid g \in \text{substrings}(f) \text{ and } \text{bs}(g) \leq \ell - 1\}. \quad (5)$$

Combining Equations (4) and (5), we get,

$$D_e \in \text{span}\{D_g \mid g \in \text{substrings}(e) \text{ and } \text{bs}(g) \leq \ell - 1\}.$$  

\[\square\]

In Lemma 26, we had assumed that the constant term $D_{i0}$ is invertible for every block $D_i$. In the next subsection, we will show how to achieve this invertibility and low-support concentration within each block $D_i$.

**5.1. Achieving invertibility and low-support concentration through shifting.** Let $D' := D(x + \phi(t))$. Then, $D' = \prod_{i=1}^d D'_i$ and $D'_{i0}$ is the constant part of $D'_i$. Shifting will serve two purposes.

- Recall that for Lemma 26, we need invertibility of the constant term $D'_{i0}$ in $D'_i$ for all $i \in [d]$.
- $D'_i$ should have low-support concentration after shifting.

Now, we want a shift for $D_i$ which would ensure that $\text{det}(D'_{i0}) \neq 0$ and that $D'_i$ has low-support concentration. For both the goals we use the sparsity of the polynomial.

**Definition 27.** For a polynomial $p$, let its sparsity set $S(p)$ be the set of monomials in $p$ with nonzero coefficients and $s(p)$ be its sparsity, i.e. $s(p) = |S(p)|$. Let $S^w(p) := \{m_1 \cdots m_w \mid m_i \in S(p), \forall i \in [w]\}$.

A map $\phi$ over $t$ separates all the monomials in a set $S$ if for any two monomials $t^{e_1}, t^{e_2} \in S$, $\phi(t^{e_1}) \neq \phi(t^{e_2})$.

Let us now characterize the shift which makes the determinant of $D'_{i0}$ nonzero.

**Lemma 28.** Suppose $D_i$ is invertible. Let $\phi: t \mapsto \{t^i\}_{i=0}^\infty$ be a monomial map which separates all the monomials in $S^w(D_i)$. Then, the constant term $D'_{i0}$ of the shifted polynomial $D'_i := D_i(x + \phi(t))$ is invertible.

**Proof.** Observe that $S(\text{det}(D_i)) \subseteq S^w(D_i)$.

Since $\phi$ separates all the monomials in $\text{det}(D_i(t))$, $\text{det}(D_i) \neq 0$ implies that $\text{det}(D_i|_{x=\phi(t)}) \neq 0$. Hence, $\text{det}(D'_{i0}) = \text{det}(D_i|_{x=\phi(t)}) \neq 0$. \[\square\]

Gurjar et al. proved in [GKST14, Lemma 19] that shifting by a basis isolating weight assignment gives concentration. The proof of Lemma 30 uses this.

**Lemma 29** (Isolation to concentration, [GKST14]). Let $D(x)$ be a polynomial over a $k$-dimensional algebra $k_k$. Let $w$ be basis isolating weight assignment for $D$ (Definition 5). Then, $D(x + t^w)$ has $\lceil \log(k + 1) \rceil$-concentration.
Recall that $\ell' := \log(w^2) + 1$.

**Lemma 30.** Let $\phi : t \mapsto \{t^i\}_{i=0}^{\infty}$ be a monomial map which separates all the monomials in $S(D_i)$. Then, $D'_i := D_i(x + \phi(t))$ is $\ell'$-concentrated.

**Proof.** $D_i$ is a polynomial over a $w^2$-dimensional algebra, $F^{w \times w}$. A map $\phi$ which separates all the monomials in $S(D_i)$ is trivially a basis isolating weight assignment for $D_i$. Thus, by Lemma 29, $D_i(x + \phi(t))$ is $(\log w^2 + 1)$-concentrated. \qed

We will now show how to find such a map $\phi$.

**Lemma 31.** Let $D(x) = \prod_{i=1}^d D_i(x_i)$ be a polynomial in $F^{w \times w}[x]$ such that for all $i \in [d]$, $\det(D_i) \neq 0$, $D_i$ has degree bounded by $\delta$ and the sparsity $s(D_i) \leq s$. Let $M := n^2 s^{2w} \log(w \delta)$. There is a set of $M$ monomial maps with degree bounded by $2M \log M$ such that for at least one of the maps $\phi$, all $D_i$’s are $\ell'$-concentrated and all $D'_i$’s are invertible, where $D' = D(x + \phi(t))$.

**Proof.** We will provide a map $\phi$ that satisfies the pre-conditions of Lemmas 28 and 30. This will ensure that all $D_i$’s are $\ell'$-concentrated and all $D'_i$’s are invertible.

Observe that a map which separates all the monomials in $S^w(D_i)$ also separates all the monomials in $S(D_i)$. This can be proved by considering the two monomials $M_1 := m_1 m_2 \ldots m_w$ and $M'_1 := m'_1 m_2 \ldots m_w$, where $m_j \in S(D_i), \forall j \in [w]$ and $m'_1 \in S(D_i)$. $M_1, M'_1 \in S^w$. Thus, if $\phi$ separates $M_1$ and $M'_1$, then $\phi$ should also separate $m_1$ and $m'_1$.

Hence, it is enough if $\phi$ separates all the monomial pairs in $S^w(D_i)$, for $i \in [d]$ simultaneously. There are $n$ variables, the number of monomial pairs is $\leq d \cdot s^{2w} \leq n \cdot s^{2w}$ and degree of the monomials (in the determinant of $D_i$s) is bounded by $w \cdot \delta$. Hence, by Lemma 4, $M = n^2 s^{2w} \log(w \delta)$ suffices. \qed

**5.2. Concentration in $D(x)$.** Now, we want to show that if $D(x) = \prod_{i=1}^d D_i$ has low-block-concentration, and moreover if each $D_i$ has low-support concentration, then $D(x)$ has an appropriate low-support concentration.

**Lemma 32 (Composition).** If $D(x)$ has $\ell$-block-concentration and $D_i(x_i)$ has $\ell'$-support concentration for all $i \in [d]$ then $D(x)$ has $\ell\ell'$-support concentration.

**Proof.** We have to prove that the any monomial $x^c$,

$$D_c := \text{coef}_D(x^c) \in \text{span}\{\text{coef}_D(x^g) \mid s(g) < \ell\ell'\}.$$

Since $D(x)$ has $\ell$-block-concentration,

$$D_c \in \text{span}\{D_f \mid \text{bs}(f) < \ell\}. \quad (6)$$

Recall that as $D_i$’s are polynomials over disjoint sets of variables, any coefficient $D_f$ in $D(x)$ can be written as

$$D_f = \prod_{i=1}^d D_{if_i}, \quad (7)$$

where $f = (f_1, f_2, \ldots, f_d)$ and $D_{if_i}$ is the coefficient corresponding to the monomial $x_i^{f_i}$ in $D_i$ for all $i \in [d]$. Also, $|\{i : f_i \neq 0\}| < \ell$.

From $\ell'$-support concentration of $D_i(x_i)$, we know that for any coefficient $D_{if_i}$,

$$D_{if_i} \in \text{span}\{D_{ig_i} \mid g_i \in \mathbb{Z}_+^{n_i}, s(g_i) \leq \ell' - 1\}. \quad (8)$$
Using Equations (7) and (8), we can write the following for any coefficient $D_f$:

$$D_f \in \text{span} \left\{ \prod_{i=1}^{d} D_{ig_i} \mid g_i \in \mathbb{Z}_+^n, s(g_i) \leq \ell' - 1, \forall i \in [d] \right\}.$$  

and $g_i = 0, \forall i \notin bS(f)$.

Note that the product $\prod_{i=1}^{d} D_{ig_i}$ will be the coefficient of a monomial $x^g$ such that $bS(g) \subseteq bS(f)$ because $g_i = 0, \forall i \notin bS(f)$. Clearly, if $s(g_i) \leq \ell' - 1, \forall i \in bS(f)$ then $s(g) \leq (\ell' - 1)bs(f)$. So, one can write

$$D_f \in \text{span}\{D_g \mid g \in \mathbb{Z}_+^n, s(g) \leq (\ell' - 1)bs(f)\}. \tag{9}$$

Using Equations (6) and (9), we can write for any coefficient $D_e$,

$$D_e \in \text{span}\{D_g \mid g \in \mathbb{Z}_+^n, s(g) \leq (\ell' - 1)(\ell - 1)\}.$$

\[ \square \]

We are now ready to go to the final step of the proof - getting the actual hitting set.

5.3. From Concentration to Hitting Set. Let $C(x) = D_0^TDD_{d+1} \in \mathbb{F}[x]$.
Since any coefficient $\text{coef}_C(x^f)$ in $C$ can be written as $D_0^T \text{coef}_D(x^f)D_{d+1}$, we get the following Lemma.

LEMMA 33 (Concentration in $C$). Let $C(x) = D_0^TDD_{d+1} \in \mathbb{F}[x]$ be a polynomial with $D_0, D_{d+1} \in \mathbb{F}^w$. If $D(x)$ has $\ell' \text{-concentration then } C(x) \text{ has } \ell \ell' \text{-concentration.}$

Now, we come back to the proof of Theorem 3. From Lemmas 31, 26, 32 and 33, we get $\text{poly}(ns^w \log(w \delta))$ maps, such that for at least one map $\phi : t \rightarrow \{t_i\}_{i=0}^\infty$, $C'(x) = C(x + \phi(t))$ is $(w^2(\log w^2 + 1))$-concentrated. The degree of $t$ is bounded by $\text{poly}(ns^w \log(w \delta))$. Hence, by Lemma 23 we get a hitting set for $C'(x) = C(x + \phi(t))$ of size $(n\delta)^{O(w^2 \log w)}$. Each of these evaluations of $C$ will be a polynomial in $t$ with degree bounded by $\text{poly}(ns^w \log(w \delta))$. Hence, total time complexity becomes $\text{poly}(s^w (n\delta)^{O(w^2 \log w)})$.

For the proof of Remark 2, observe that when the $D_i$s are univariate, $D'_i$s are 1-concentrated and sparsity $s \leq \delta$. Thus, when the $D_i$s are univariate, we get a $(n\delta)^{O(w^2 \log w)}$ sized hitting-set.

5.4. Width-2 Read Once ABP. In the previous section, the crucial part in finding a hitting-set for an ROABP is the assumption that the matrix product $D(x)$ is invertible. Now, we will show that for width-2 ROABP, this assumption is not required. Via a factorization property of $2 \times 2$ matrices, we will show that PIT for width-2 sparse-factor ROABP reduces to PIT for width-2 sparse-invertible-factor ROABP. This factorization of width-2 ABPs has also been studied by Allender and Wang [AW11]. But their reduction cannot maintain the sparsity of the matrix entries.

LEMMA 34 (2 $\times$ 2 invertibility). Let $C(x) = D_0^T \left( \prod_{i=1}^{d} D_i \right) D_{d+1}$ be a polynomial computed by a width-2 sparse-factor ROABP. Then for some nonzero $\alpha \in \mathbb{F}[x]$ and some $m \leq d$, we can write $\alpha(x)C(x) = C_1(x)C_2(x) \cdots C_{m+1}(x)$, where each of the $C_i$s are of the form $P_i^T Q_i R_i$. $Q_i \in \mathbb{F}^{2 \times 2}[x]$ is a polynomial computed by a width-2 sparse-invertible-factor ROABP, $P_i, R_i \in \mathbb{F}^{2 \times 2}[x]$, and $P_i, Q_i$ and $R_i$ are over disjoint sets of variables for all $i \in [m+1]$. 
In other words, we can write
\[
\alpha P \quad \text{where} \quad \alpha = \frac{1}{a_i} [a_i b_i].
\]
In other words, we can write \( \alpha_i D_i = A_i B_i^\top \), where \( A_i, B_i \in \mathbb{F}^2[x_i] \) and \( 0 \neq a_i \in \{a_i, b_i, c_i, d_i\} \). Note that \( s(\alpha_i), s(A_i), s(B_i) \leq s(D_i) \). Let us say that the set of non-invertible \( D_i \)'s is \( \{D_{i_1}, D_{i_2}, \ldots, D_{i_m}\} \). Writing all of them in the above form we get,
\[
C(x) \prod_{j=1}^m \alpha_{ij} = \prod_{j=1}^{m+1} C_j,
\]
where
\[
C_j := \begin{cases} 
D_0^\top \left( \prod_{i=1}^{j-1} D_i \right) A_{ij} & \text{if } j = 1, \\
B_{ij-1}^\top \left( \prod_{i=j-1}^{j-1} D_i \right) A_{ij} & \text{if } 2 \leq j \leq m, \\
B_{im}^\top \left( \prod_{i=m+1}^d D_i \right) D_{d+1} & \text{if } j = m+1.
\end{cases}
\]
Clearly, for all \( j \in [m+1] \), \( \left( \prod_{i=j}^{j} D_i \right) \) can be computed by a sparse-invertible-factor ROABP. The required \( P_j \) is \( B_{j} \), and the required \( Q_j \) is \( A_{ij} \). Moreover, \( P_j, Q_j \) and \( R_j \) are over disjoint variables for all \( j \).

Now, from the above Lemma it is easy to construct a hitting-set. First we write a general result about hitting-sets for a product of polynomials from some class [SY10, Observation 4.1].

**Lemma 35 (Lagrange interpolation).** Suppose \( \mathcal{H} \) is a hitting-set for a class of polynomials \( \mathcal{C} \). Let \( C(x) = C_1(x)C_2(x) \cdots C_m(x) \), be a degree \( \delta' \) polynomial over \( \mathbb{F} \), where \( C_i \in \mathcal{C} \) for all \( i \in [m] \). There is a hitting-set of size \( \delta' |\mathcal{H}| + 1 \) for \( C(x) \).

**Proof.** Let \( h = |\mathcal{H}| \) and \( \mathcal{H} = \{\alpha_1, \alpha_2, \ldots, \alpha_h\} \). Let \( B := \{\beta_i\}_{i=1}^h \) be a set of constants. The Lagrange interpolation \( \alpha(u) \) of the points in \( \mathcal{H} \) is defined as follows
\[
\alpha(u) := \sum_{i=1}^h \prod_{j \neq i} (u - \beta_j) \alpha_i.
\]
The key property of the interpolation is that when we put \( u = \beta_i \), \( \alpha(\beta_i) = \alpha_i \) for all \( i \in [h] \). For any \( a \in [m] \), we know that \( C_a(\alpha_i) \neq 0 \), for some \( i \in [h] \). Hence, \( C_a(\alpha(u)) \) as a polynomial in \( u \) is nonzero because \( C_a(\alpha(\beta_i)) = C_a(\alpha_i) \neq 0 \). So, we can say \( C(\alpha(u)) \neq 0 \) as a polynomial in \( u \).

Degree of \( \alpha(u) \) is \( h - 1 \). So, degree of \( C(\alpha(u)) \) in \( u \) is bounded by \( \delta'(h - 1) \). We can put \( \delta' h \) distinct values of \( u \) to get a hitting-set for \( C(\alpha(u)) \).

Consider the polynomial \( C(x) = P(x)^\top Q(x)R(x) \), where \( Q \in \mathbb{F}^{w \times w} \) is a polynomial computed by a width-\( w \) \( s \)-sparse-invertible-factor ROABP, \( P, R \in \mathbb{F}^w \), and \( P, Q \) and \( R \) are over disjoint sets of variables for all \( i \in [m + 1] \). It is similar to the polynomial described in Theorem 3, except that \( P \) and \( R \) are now polynomials over \( \mathbb{F}^w \). By adapting the proof of Theorem 3, we can show a hitting set of size \( \text{poly}(n \delta s) \wedge \log w \) in such a model. Lemma 30 can also be applied to \( P \) and \( R \) to make...
them \((\log w^2 + 1)\)-concentrated. Since \(Q\) is \(w^2\)-block-concentrated by Lemma 26, \(C\) would be \((w^2 + 2)\)-block-concentrated. The rest of the proof goes through similarly.

We thus get the following Lemma.

**Lemma 36.** Let \(C(x) = P(x)^\top Q(x)R(x)\), where \(Q \in \mathbb{F}^{w \times w}[x]\) is a polynomial computed by a width-\(w\) \(s\)-sparse-invertible-factor ROABP, \(P, R \in \mathbb{F}^w[x]\), and \(P, Q\) and \(R\) are over disjoint sets of variables. Let the degree of each layer in \(Q\) be bounded by \(\delta\) and the sparsity of each layer in \(Q\) be bounded by \(s\). Then there is a hitting-set of size \(\text{poly}((n\delta s)w^2 \log w)\), for \(C(x)\).

Note that a hitting-set for \(\alpha(x)C(x)\) is also a hitting-set for \(C(x)\) if \(\alpha\) is a nonzero polynomial. We get a hitting-set for each of the factors by Lemma 36. Lemma 34 tells us how to factorize a width-2 ROABP into a product of width-2 invertible ROABPs. Combining these results with Lemma 35 we get the following.

**Theorem 37.** Let \(C(x) = D_0^\top(x_0)(\prod_{i=1}^d D_i(x_i))D_{d+1}(x_{d+1})\) be a polynomial in \(\mathbb{F}[x]\) computed by a width-2 ROABP such that for all \(1 \leq i \leq d\), \(D_i\) has degree bounded by \(\delta\) and sparsity \(s(D_i)\) bounded by \(s\). Then there is a hitting-set of size \(\text{poly}(n\delta s)\).

6. **Discussion.** The first open problem is to do basis isolation for ROABP with only a polynomially large weight assignment. Also, our technique of finding a basis isolating weight assignment seems general. It needs to be explored, for what other classes can it be applied. In particular, can it be used to solve depth-3 multilinear circuits? An easier question, perhaps, could be to improve Theorem 18 to get a truly blackbox PIT for the 2-base-sets-1-distance model.

Another question is whether we can find a similar result in the boolean setting, i.e. get a pseudorandom generator for unknown order ROBP with seed length same as the known order case.

In the case of constant width ROABP, we could show constant-support concentration, but only after assuming that the factor matrices are invertible. It seems that the invertibility assumption restricts the computing power of ROABP significantly. It is desirable to have low-support concentration without the assumption of invertibility.

As in the case of invertible ROABP and width-2 ROABP, analogous results hold in the boolean setting, it will be interesting to see if there is some connection, at the level of techniques, between pseudorandom generators for boolean and arithmetic models.

7. **Acknowledgements.** We thank Chandan Saha for suggestions to improve this paper. Several useful ideas about \(\Delta\)-distance circuits and base sets came up during discussions with him. We thank Michael Forbes for suggesting a possible reduction from \(\Delta\)-distance circuits to ROABP (Lemma 14). We thank anonymous reviewers for the various simplifications, improvements and useful suggestions. RG thanks TCS research fellowship for support. NS thanks DST-SERB for the funding support.

Noam Nisan, Lower bounds for non-commutative computation (extended abstract), Pro-
Appendix A. Separating a set of monomials.

Lemma 4 (restated). Let $\mathcal{M}$ be the set of all monomials in $n$ variables $x = \{x_1, x_2, \ldots, x_n\}$ with maximum individual degree $\delta$. For any value $a$, there exists a (constructible) set of $N := n \log(\delta + 1)$ weight functions $w : x \to \{1, \ldots, 2N \log N\}$, such that for any set $A$ of pairs of monomials from $\mathcal{M}$ with $|A| = a$, at least one of the weight functions separates all the pairs in $A$, i.e., $\forall (m, m') \in A$, $w(m) \neq w(m')$.

Proof. Since we want to separate the $n$-variate monomials with maximum individual degree $\delta$, we use the naive Kronecker map $W : x_i \mapsto (\delta + 1)^{i-1}$ for all $i \in [n]$. It can be easily seen that $W$ will give distinct weights to any two monomials (with maximum individual degree $\delta$). But, the weights given by $W$ are exponentially high.

So, we take the weight function $W$ modulo $p$, for many small primes $p$. Each prime $p$ leads to a different weight function. That is our set of candidate weight functions. We need to bound the number $N$ of primes that ensures that at least one of the weight functions separates all the monomial pairs in $A$. We choose the smallest $N$ primes, say $\mathcal{P}$ is the set. By the effective version of the Prime Number Theorem, the highest value in the set $\mathcal{P}$ is less than $2N \log N$. 

28
To bound the number $N$ of primes: We want a $p \in \mathcal{P}$ such that $\forall (m, m') \in A$, $W(m) - W(m') \not\equiv 0 \pmod{p}$. Which means,

$$
\exists p \in \mathcal{P}, \ p \nmid \prod_{(m, m') \in A} (W(m) - W(m')).
$$

In other words,

$$
\prod_{p \in \mathcal{P}} p \nmid \prod_{(m, m') \in A} (W(m) - W(m')).
$$

This can be ensured by setting $\prod_{p \in \mathcal{P}} p > \prod_{(m, m') \in A} (W(m) - W(m'))$. There are $|A|$ such monomial pairs and each $W(m) < (\delta + 1)^n$. Also, $\prod_{p \in \mathcal{P}} p > 2^N$. Hence, $N = na \log(\delta + 1)$ suffices. \(\Box\)
