Abstract

We study the problem of factoring univariate polynomials over finite fields. Under the assumption of the Extended Riemann Hypothesis (ERH), Gao [Gao01] designed a polynomial time algorithm that fails to factor only if the input polynomial satisfies a strong symmetry property, namely *square balance*. In this paper, we propose an extension of Gao's algorithm that fails only under an even stronger symmetry property. We also show that our property can be used to improve the time complexity of best deterministic algorithms on most input polynomials. The property also yields a new randomized polynomial time algorithm.

1 Introduction

We consider the problem of designing an efficient deterministic algorithm for factoring a univariate polynomial, with coefficients taken from a finite field. The problem reduces in polynomial time to the problem of factoring a monic, square-free and completely splitting polynomial $f(x)$ with coefficients in a prime field F_p (see [Ber70], [LN94]). Although there are efficient polynomial time randomized algorithms for factoring $f(x)$ (see works of [Ber70], [CZ81], [vzGS92], [KS95]), as yet there is no deterministic polynomial time algorithm even under the assumption of the Extended Riemann Hypothesis (ERH). In this paper we will assume that ERH is true and $\xi_1, \xi_2, \dots, \xi_n$ are the n distinct roots of the input polynomial f ,

$$f(x) = \prod_{i=1}^n (x - \xi_i) \quad \text{where } \xi_i \in F_p$$

In 2001, [Gao01] gave a deterministic factoring algorithm that fails to find nontrivial factors of f in polynomial time, if f belongs to a restricted class of polynomials, namely *square balanced polynomials*. Motivated by the work [Gao01], we have defined a proper subclass of square balanced polynomials, namely *cross balanced polynomials*, such that polynomials that are not cross balanced, can be factored deterministically in polynomial time, under the assumption of the ERH.

Our contribution can be summarized as follows. Let f be a monic, square-free and completely splitting polynomial in $F_p[x]$ with n roots ξ_1, \dots, ξ_n . Our factoring algorithm uses an arbitrary (but deterministically chosen) collection of $k = (n \log p)^{O(1)}$ ($n = \deg(f)$) small degree auxiliary polynomials $p_1(\cdot), \dots, p_k(\cdot)$, and from each $p_l(\cdot)$ ($1 \leq l \leq k$) and f it implicitly constructs a simple n -vertex digraph G_l such that, (for $l > 1$) G_l is a subgraph (not necessarily a proper subgraph) of G_{l-1} . A proper factor of f is efficiently retrieved if any one of the graphs is either not regular, or is regular with in degree and out degree of every vertex less than a chosen constant c . This condition of regularity of all the k graphs imposes a *tight symmetry condition* on the roots of f , and we point out that this may be exploited to improve the worst case time complexity of the best

known deterministic factoring algorithms. Further, we show that if the polynomials $p_l(\cdot)$ ($1 \leq l \leq k$) are randomly chosen then the symmetry breaks with high probability and our algorithm works in randomized polynomial time. We call the checking of this symmetry condition a *balance test*.

We now present a little more details. Define the sets Δ_i for $1 \leq i \leq n$ as,

$$\Delta_i = \{1 \leq j \leq n : j \neq i, \sigma((\xi_i - \xi_j)^2) = -(\xi_i - \xi_j)\}$$

where σ is the square root algorithm described in [Gao01] (see section 2.4). The polynomial f is called a *square balanced polynomial* (by [Gao01]) if $\#\Delta_1 = \dots = \#\Delta_n$. For $l > 1$, define polynomial f_l as,

$$f_l = \prod_{i=1}^n (x - p_l(\xi_i))$$

where $p_l(\cdot)$ is an arbitrary but deterministically chosen polynomial with degree bounded by $(n \log p)^{O(1)}$. Further, $p_{l_1}(\cdot) \neq p_{l_2}(\cdot)$ for $l_1 \neq l_2$, and f_1 is taken to be f i.e. $p_1(y) = y$. Assume that, for a given $k = (n \log p)^{O(1)}$, for every l , $1 \leq l \leq k$, polynomial $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free and square balanced polynomial and $d_l > 0$. Later, we show that, if f_l is not of the above form then a proper factor of f can be retrieved efficiently. For each polynomial f_l , $1 \leq l \leq k$, define the sets $\Delta_i^{(l)}$ for $1 \leq i \leq n$ as,

$$\Delta_i^{(l)} = \{1 \leq j \leq n : p_l(\xi_i) \neq p_l(\xi_j), \sigma((p_l(\xi_i) - p_l(\xi_j))^2) = -(p_l(\xi_i) - p_l(\xi_j))\}$$

Further, define the sets $D_i^{(l)}$ iteratively over l as,

$$\begin{aligned} D_i^{(1)} &= \Delta_i^{(1)} \\ \text{For } l > 1, D_i^{(l)} &= D_i^{(l-1)} \cap \Delta_i^{(l)} \\ \text{If } D_i^{(l)} &= \phi \text{ for all } i, 1 \leq i \leq n, \text{ then redefine } D_i^{(l)} \text{ as } D_i^{(l)} = D_i^{(l-1)}. \end{aligned}$$

For $1 \leq l \leq k$, let G_l be a directed graph with n vertices v_1, \dots, v_n , such that there is an edge from v_i to v_j if and only if $j \in D_i^{(l)}$. Note that, G_l is a subgraph of G_{l-1} for $1 < l \leq k$. Denote the in degree and out degree of a vertex v_i by $\text{indeg}(v_i)$ and $\text{outdeg}(v_i)$, respectively. We say that the graph G_l is *regular* (or *t-regular*) if $\text{indeg}(v_1) = \text{outdeg}(v_1) = \dots = \text{indeg}(v_n) = \text{outdeg}(v_n) = t$. Here t will be called the *regularity* of G_l . The following theorem is proved in this paper.

Theorem 1.1 *Polynomial f can be factored into nontrivial factors in time $l \cdot (n \log p)^{O(1)}$ if G_l is not regular for some l , $1 \leq l \leq k$. Further, if G_1, \dots, G_k are all regular and for at least $\lceil \log_2 n \rceil$ of the graphs we have $G_l \neq G_{l-1}$ ($1 < l \leq k$), then f can be factored in $k \cdot (n \log p)^{O(1)}$ time.*

Note that, G_1 is regular if and only if f is square balanced, as $\Delta_i^{(1)} = \Delta_i$, for $1 \leq i \leq n$ and G_1 is in fact a regular tournament.

Suppose $f(y)$ splits as $f(y) = (y - X) \cdot f'(y)$ in the quotient ring $R = \frac{F_p[x]}{(f)}$ where $X = x \bmod f$. Our algorithm iteratively tests graphs G_1, G_2, \dots so on, to check if any one of them is irregular. If at the l^{th} iteration graph G_l turns out to be irregular, then a proper factor of f is obtained in polynomial time. However, if G_l is regular, then the algorithm returns a nontrivial monic factor $g_l(y)$ of $f'(y)$ with degree equal to the regularity of G_l . Moreover, $g_l(y)$ is also a factor of (although may be equal to) $g_{l-1}(y)$, the factor obtained at the $(l-1)^{\text{th}}$ iteration, and it can be ensured that if $g_l(y)$ is a proper factor of $g_{l-1}(y)$ (which happens iff $G_l \neq G_{l-1}$) then $\text{deg}(g_l(y)) \leq \frac{1}{2} \cdot \text{deg}(g_{l-1}(y))$. Thus, if the graphs repeatedly turn out to be regular (which in itself is a stringent condition) and for at least

$\lceil \log_2 n \rceil$ times it happen that $G_l \neq G_{l-1}$, for $1 < l \leq k$, then we obtain a nontrivial linear factor $g(y)$ of $f'(y)$. The element $-g(0)$ defines a nontrivial *endomorphism* in the ring R , and by using a result from [Evd94] (lemma 9 in [Evd94]) we can find a proper factor of f in polynomial time. Further, if for only $\epsilon \lceil \log_2 n \rceil$ times we get $G_l \neq G_{l-1}$ ($1 < l \leq k$) for some ϵ , $0 < \epsilon \leq 1$, then we obtain a nontrivial factor $g(y)$ of $f'(y)$ with degree at most $\frac{n^{1-\epsilon}}{2}$. Now if we apply Evdokimov's algorithm (see appendix B) on $g(y)$ (instead of $f'(y)$), we can get a proper factor of f in time $(n^{\frac{(1-\epsilon)^2}{2} \log n + \epsilon + c_1} \log p)^{c_2}$ (c_1 and c_2 are constants). For most polynomials $\epsilon > 0$ (i.e. at least about $\frac{1}{\log n}$) and this gives an improvement over the time complexity of $(n^{\frac{1}{2} \log n + c_1} \log p)^{c_2}$ in [Evd94] (c_1, c_2 are the same constants).

Assuming $n \ll p$, all the best known deterministic algorithms (e.g. [Evd94], [CH00]) use computations in rings with large dimensions over F_p to get smaller degree factors of $f'(y)$. Unlike these approaches, the balance test is an attempt to exploit an asymmetry among the roots of the input polynomial to obtain smaller degree factors of $f'(y)$ without carrying out computations in rings with large dimensions over F_p . This attribute of our approach yields a better time complexity for most polynomials in a way as discussed in the last paragraph.

It is sufficient to choose the auxiliary polynomials $p_l(y)$, $1 < l \leq k$, in such a way that the graphs, if regular, are not all the same for too long, if their regularities are large. An efficient and deterministic construction of such auxiliary polynomials will immediately imply that factorization of univariate polynomials over finite fields can be done in deterministic polynomial time under ERH. In this paper we assume that the auxiliary polynomials are arbitrary but deterministically chosen polynomials with degree bounded by $(n \log p)^{O(1)}$. (We also show that, if random choices of auxiliary polynomials are allowed then our algorithm works in randomized polynomial time.) For the graphs to be all regular and equal, the roots of f must satisfy a tight symmetry condition (given by equal sizes of all the sets $D_i^{(l)}$, for $1 \leq i \leq n$ and $1 \leq l \leq k$) and it is only then that our algorithm fails to factor f .

Definition 1.1 *A polynomial f is called k -cross balanced, for $k > 0$, if for every l , $1 \leq l \leq k$, polynomial $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free, square balanced polynomial with $d_l > 0$, and graph G_l is regular.*

It follows from the definition that, 1-cross balanced polynomials form the class of square balanced polynomials. Let $k = (n \log p)^{O(1)}$ be some fixed polynomial in n and $\log p$. A polynomial f is called *cross balanced* if it is k -cross balanced and regularity of graph G_k is greater than c , where c is some fixed constant. From theorem 1.1 and [Evd94] it follows that, polynomials that are not cross balanced can be factored deterministically in polynomial time.

In section 2 we discuss the preliminary concepts and in section 3 we state our algorithm and work out the analysis.

2 Preliminaries

Assume that f is a monic, square-free and completely splitting polynomial over F_p and $R = \frac{F_p[x]}{(f)}$ is the quotient ring consisting of all polynomials modulo f .

2.1 Primitive Idempotents

Elements χ_1, \dots, χ_n of the ring R are called the *primitive idempotents* of R if, $\sum_{i=1}^n \chi_i = 1$ and for $1 \leq i, j \leq n$, $\chi_i \cdot \chi_j = \chi_i$ if $i = j$ and 0 otherwise. By Chinese Remaindering

theorem, $R \cong F_p \oplus \dots \oplus F_p$ (n times), such that every element in R can be uniquely represented by an n -tuple of elements in F_p . Addition and multiplication between two elements in R can be viewed as componentwise addition and multiplication of the n -tuples. Any element $\alpha = (a_1, \dots, a_n) \in R$ can be equated as, $\alpha = \sum_{i=1}^n a_i \chi_i$ where $a_i \in F_p$. Let $g(y)$ be a polynomial in $R[y]$ given by,

$$g(y) = \sum_{i=0}^m \gamma_i y^i \quad \text{where } \gamma_i \in R \text{ and}$$

$$\gamma_i = \sum_{j=1}^n g_{ij} \chi_j \quad \text{where } g_{ij} \in F_p \text{ for } 0 \leq i \leq m \text{ and } 1 \leq j \leq n.$$

Then $g(y)$ can be alternatively represented as,

$$g(y) = \sum_{j=1}^n g_j(y) \chi_j \quad \text{where } g_j(y) = \sum_{i=0}^m g_{ij} y^i \in F_p[y] \text{ for } 1 \leq j \leq n.$$

The usefulness of this representation is that, operations on polynomials in $R[y]$ (multiplication, gcd etc.) can be viewed as componentwise operations on polynomials in $F_p[y]$.

2.2 Characteristic Polynomial

Consider an element $\alpha = \sum_{i=1}^n a_i \chi_i \in R$ where $a_i \in F_p$, $1 \leq i \leq n$. α defines a linear transformation on the vector space R (over F_p), mapping an element $\beta \in R$ to $\alpha\beta \in R$. The characteristic polynomial of α (viewed as a linear transformation) is independent of the choice of basis and is equal to

$$c_\alpha(y) = \prod_{i=1}^n (y - a_i),$$

In order to construct c_α one can use $1, X, X^2, \dots, X^{n-1}$ as the basis in R and form the matrix (m_{ij}) where $\alpha \cdot X^{j-1} = \sum_{i=1}^n m_{ij} X^{i-1}$, $m_{ij} \in F_p$, $1 \leq i, j \leq n$. Then c_α is constructed by evaluating $\det(y \cdot I - (m_{ij}))$ at n distinct values of y and solving for the n coefficients of c_α using linear algebra. The process takes only polynomial time. The notion of characteristic polynomial extends even to higher dimensional algebras over F_p .

2.3 GCD of Polynomials

Let $g(y) = \sum_{i=1}^n g_i(y) \chi_i$ and $h(y) = \sum_{i=1}^n h_i(y) \chi_i$ be two polynomials in $R[y]$, where $g_i, h_i \in F_p[y]$ for $1 \leq i \leq n$. Then, gcd of g and f is defined as,

$$\gcd(g, f) = \sum_{i=1}^n \gcd(g_i, h_i) \chi_i$$

The following lemma was shown in [Gao01].

Lemma 2.1 ([Gao01]) *Given two polynomials $g, h \in R[y]$, $\gcd(g, h)$ can be computed in time polynomial in the degrees of the polynomials, n and $\log p$.*

2.4 Gao's Algorithm

Let $R = \frac{F_p[x]}{(f)} = F_p[X]$ where $X = x \bmod f$ and suppose that $f(y)$ splits in R as, $f(y) = (y - X)f'(y)$. Define quotient ring S as, $S = \frac{R[y]}{(f')} = R[Y]$ where $Y = y \bmod f'$. S is an elementary algebra over F_p with dimension $n' = n(n - 1)$. Gao [Gao01] described an algorithm σ for taking square root of an element in S . If $p - 1 = 2^e w$ where $e \geq 1$ and w is odd, and η is a primitive 2^e -th root of unity, then σ has the following properties:

1. Let $\mu_1, \dots, \mu_{n'}$ be primitive idempotents in S and $\alpha = \sum_{i=1}^{n'} a_i \mu_i \in S$ where $a_i \in F_p$. Then, $\sigma(\alpha) = \sum_{i=1}^{n'} \sigma(a_i) \mu_i$.
2. Let $a = \eta^u \theta$ where $\theta \in F_p$ with $\theta^w = 1$ and $0 \leq u < 2^e$. Then $\sigma(a^2) = a$ iff $u < 2^{e-1}$.

When $p \equiv 3 \pmod{4}$, $\eta = -1$ and property 2 implies that $\sigma(a^2) = a$ for $a \in F_p$ iff a is a quadratic residue in F_p .

Algorithm 1 [Gao01]

Input: A polynomial $f \in F_p[x]$.

Output: A proper factor of f or output that “ f is square balanced”.

1. Form X, Y, R, S as before.
2. Compute $C = \frac{1}{2}(X + Y + \sigma((X - Y)^2)) \in S$.
3. Compute the characteristic polynomial $c(y)$ of C over R .
4. Decompose $c(y)$ as $c(y) = h(y)(y - X)^t$, where t is the largest possible.
5. If $h(X)$ is a zero divisor in R then find a proper factor of f , otherwise output that “ f is square balanced”.

It was shown in [Gao01] that algorithm 1 fails to find a proper factor of f if and only if f is square balanced. Moreover, it follows from the analysis in [Gao01] (see theorem 3.1 in [Gao01]) that, when f is square balanced the polynomial $h(y)$ takes the form,

$$h(y) = \sum_{i=1}^n \left[\prod_{j \in \Delta_i} (y - \xi_j) \right] \chi_i$$

where $\Delta_i = \{j : j \neq i, \sigma((\xi_i - \xi_j)^2) = -(\xi_i - \xi_j)\}$ and $\#\Delta_i = \frac{n-1}{2}$ for all $i, 1 \leq i \leq n$.

3 Our Algorithm and Analysis

In this section, we describe our algorithm for factoring polynomial f . We show that the algorithm fails to factor f in $k \cdot (n \log p)^{O(1)}$ time if and only if f is k -cross balanced and regularity of G_k is greater than c . The algorithm involves k polynomials, $f = f_1, \dots, f_k$, where polynomial $f_l, 1 < l \leq k$, is defined as,

$$f_l = \prod_{i=1}^n (x - p_l(\xi_i))$$

$p_l(\cdot)$ is an arbitrary but deterministically fixed polynomial with degree bounded by $(n \log p)^{O(1)}$ and $p_{l_1}(\cdot) \neq p_{l_2}(\cdot)$ for $l_1 \neq l_2$. The polynomial f_l can be constructed in polynomial time by considering the element $p_l(X)$ in $R = \frac{F_p[x]}{(f)} = F_p[X]$, where $X = x \bmod f$, and then computing its characteristic polynomial over F_p .

Lemma 3.1 *If f_l is not of the form $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free, square balanced polynomial and $d_l > 0$, then a proper factor of f can be retrieved in polynomial time.*

Proof: See appendix A ■

Therefore, assume that $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free, square balanced polynomial and $d_l > 0$. Let,

$$\tilde{f}_l = \prod_{j=1}^{m_l} (x - p_l(\xi_{s_j}))$$

where $p_l(\xi_{s_1}), \dots, p_l(\xi_{s_{m_l}})$ are all distinct and $m_l = \frac{n}{d_l}$. Algorithm 1 works with \tilde{f}_l as the input polynomial and returns a polynomial $h_l(y)$ such that,

$$h_l(y) = \sum_{j=1}^{m_l} \left[\prod_{r \in \tilde{\Delta}_j^{(l)}} (y - p_l(\xi_{s_r})) \right] \chi_j^{(l)} \quad (1)$$

where $\chi_j^{(l)}$'s are the primitive idempotents of the ring $R_l = \frac{F_p[x]}{(\tilde{f}_l)}$,

$$\tilde{\Delta}_j^{(l)} = \{1 \leq r \leq m_l : r \neq j, \sigma((p_l(\xi_{s_j}) - p_l(\xi_{s_r}))^2) = -(p_l(\xi_{s_j}) - p_l(\xi_{s_r}))\}$$

and $\#\tilde{\Delta}_j^{(l)} = \frac{m_l-1}{2}$ for $1 \leq j \leq m_l$. Assume that $p > n^2$ and n is odd, as even degree polynomials can be factored in polynomial time. In the following algorithm, parameter k is taken to be a fixed polynomial in n and $\log p$ and c is a fixed constant.

Algorithm 2 *Cross Balance*

Input: A polynomial $f \in F_p[x]$ of odd degree n .

Output: A proper factor of f or “Failure”.

- Choose $k - 1$ distinct polynomials $p_2(y), \dots, p_k(y)$ with degree greater than unity and bounded by a polynomial in n and $\log p$. (We can use any arbitrary, efficient mechanism to deterministically choose the polynomials.) Take $p_1(y) = y$.
- **for** $l = 1$ **to** k **do**.

1. Compute the characteristic polynomial, $c_\alpha(x)$, of element $\alpha = p_l(X) \in R$, over F_p and let $f_l = c_\alpha(x)$.
2. Check if f_l is of the form $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free, square balanced polynomial and $d_l > 0$. If not, then find a proper factor of f as in lemma 3.1.
3. Else, \tilde{f}_l is square balanced and algorithm 1 returns a polynomial $h_l(y) = y^t + \alpha_1 y^{t-1} + \dots + \alpha_t$ (as in equation 1), where $t = \frac{m_l-1}{2}$ and $\alpha_u \in R_l$ for $1 \leq u \leq t$.
4. Each $\alpha_u \in R_l$ is a polynomial $\alpha_u(x) \in F_p[x]$ of degree less than m_l . Compute α'_u as, $\alpha'_u = \alpha_u(p_l(x)) \bmod f$ for $1 \leq u \leq t$, and construct the polynomial $h'_l(y) = y^t + \alpha'_1 y^{t-1} + \dots + \alpha'_t \in R[y]$.
5. If $l = 1$ then assign $g_l(y) = h'_l(y) \in R[y]$ and continue the loop with the next value of l . Else, compute $g_l(y)$ as,

$$g_l(y) = \gcd(g_{l-1}(y), h'_l(p_l(y))) \in R[y].$$

6. Let $g_l(y) = \beta_{t'} y^{t'} + \dots + \beta_0$, where t' is the degree of $g_l(y)$ and $\beta_u \in R$ for $0 \leq u \leq t'$. If $t' = 0$ then make $g_l(y) = g_{l-1}(y)$ and continue the loop with the next value of l .
7. Else, $t' > 0$. If $\beta_{t'}$ is a zero divisor in R , construct a proper factor of f from $\beta_{t'}$ and stop.
8. Else, if $t' \leq c$ then use Evdokimov's algorithm ([Evd94]) on $g_l(y)$ to find a proper factor of f in $(n \log p)^{O(1)}$ time.
9. If $t' > c$, evaluate $g_l(y) \in R[y]$ at $n \cdot t'$ distinct points $y_1, \dots, y_{nt'}$ taken from F_p . Find the characteristic polynomials of elements $g_l(y_1), \dots, g_l(y_{nt'}) \in R$ over F_p as $c_1(x), \dots, c_{nt'}(x) \in F_p[x]$, respectively.

10. Construct the polynomial $r(x) = x^{nt'} + r_1x^{nt'-1} + \dots + r_{nt'} \in F_p[x]$ such that $r(y_i) = -c_i(0)$ for $1 \leq i \leq nt'$. Solve for $r_i \in F_p$, $1 \leq i \leq nt'$, using linear algebra.
11. For $0 \leq i < t'$, if $f^i(x)$ divides $r(x)$ then compute $\gcd\left(\frac{r(x)}{f^i(x)}, f(x)\right) \in F_p[x]$. If a proper factor of f is found, stop. Else, continue with the next value of l .

endfor

- If a proper factor of f is not found in the above for loop, return “Failure”.

Theorem 3.1 Algorithm 2 fails to find a proper factor f in $k \cdot (n \log p)^{O(1)}$ time if and only if f is k -cross balanced and regularity of graph G_k is greater than c .

Proof: We show that, algorithm 2 fails to find a proper factor of f at the l^{th} iteration of the loop iff f is l -cross balanced and regularity of G_l is greater than c . Recall the definitions of the sets $\Delta_i^{(l)}$ and $D_i^{(l)}$, $1 \leq i \leq n$, from section 1. The set $\Delta_i^{(l)}$ is defined as,

$$\Delta_i^{(l)} = \{1 \leq j \leq n : p_l(\xi_i) \neq p_l(\xi_j), \sigma((p_l(\xi_i) - p_l(\xi_j))^2) = -(p_l(\xi_i) - p_l(\xi_j))\}$$

And set $D_i^{(l)}$ is defined iteratively over l as,

$$\begin{aligned} D_i^{(1)} &= \Delta_i^{(1)} \\ \text{For } l > 1, D_i^{(l)} &= D_i^{(l-1)} \cap \Delta_i^{(l)} \\ \text{If } D_i^{(l)} &= \phi \text{ for all } i, 1 \leq i \leq n, \text{ then } D_i^{(l)} \text{ is redefined as } D_i^{(l)} = D_i^{(l-1)}. \end{aligned}$$

Graph G_l , with n vertices v_1, \dots, v_n , has an edge from v_i to v_j iff $j \in D_i^{(l)}$.

Algorithm 2 fails at the first iteration ($l = 1$) if and only if f is square balanced. In this case, $D_i^{(1)} = \Delta_i^{(1)} = \Delta_i$, the polynomial $g_1(y)$ is,

$$g_1(y) = h(y) = \sum_{i=1}^n \left[\prod_{j \in D_i^{(1)}} (y - \xi_j) \right] \chi_i$$

and G_1 is regular with in degree and out degree of a vertex v_i equal to $\#D_i^{(1)} = \#\Delta_i = \frac{n-1}{2}$. Thus, polynomial f is 1-cross balanced and $\deg(g_1(y)) = \frac{n-1}{2}$. If algorithm 2 fails at the l^{th} iteration, then we can assume that the polynomials $f = \tilde{f}_1, \dots, \tilde{f}_l$ are square free and square balanced (by lemma 3.1).

Suppose that, algorithm 2 fails at the l^{th} iteration. Then, $\tilde{f}_l = \prod_{j=1}^{m_l} (x - p_l(\xi_{s_j}))$ is square free and square balanced, and algorithm 1 returns the polynomial $h_l(y) \in R_l[y]$ such that,

$$h_l(y) = \sum_{j=1}^{m_l} \left[\prod_{r \in \tilde{\Delta}_j^{(l)}} (y - p_l(\xi_{s_r})) \right] \chi_j^{(l)} \quad (2)$$

where $\chi_j^{(l)}$'s are the primitive idempotents of the ring $R_l = \frac{F_p[x]}{(f)}$ and,

$$\tilde{\Delta}_j^{(l)} = \{1 \leq r \leq m_l : r \neq j, \sigma((p_l(\xi_{s_j}) - p_l(\xi_{s_r}))^2) = -(p_l(\xi_{s_j}) - p_l(\xi_{s_r}))\}$$

Let, $h_l(y) = y^t + \alpha_1 y^{t-1} + \dots + \alpha_t$, where $t = \frac{m_l-1}{2}$ and $\alpha_u \in R_l$ for $1 \leq u \leq t$. Each $\alpha_u \in R_l$ is a polynomial $\alpha_u(x) \in F_p[x]$ with degree less than m_l and if $\alpha_u = \sum_{j=1}^{m_l} a_{uj} \chi_j^{(l)}$

for $a_{uj} \in F_p$, then by Chinese Remaindering theorem (and assuming the correspondence between $\chi_j^{(l)}$ and the factor $(x - p_l(\xi_{s_j}))$ of \tilde{f}_l) we get,

$$\begin{aligned} \alpha_u(x) &= q(x)(x - p_l(\xi_{s_j})) + a_{uj} \quad \text{for some polynomial } q(x) \in F_p[x] \\ \Rightarrow \alpha_u(p_l(x)) &= q(p_l(x))(p_l(x) - p_l(\xi_{s_j})) + a_{uj} \\ \Rightarrow \alpha_u(p_l(x)) &= a_{uj} \pmod{(x - \xi)} \quad \text{for every } \xi \in \{\xi_1, \dots, \xi_n\} \text{ such that } p_l(\xi) = p_l(\xi_{s_j}) \end{aligned}$$

Suppose that, for a given i ($1 \leq i \leq n$), $j(i)$ ($1 \leq j(i) \leq m_l$) is a unique index such that, $p_l(\xi_i) = p_l(\xi_{s_{j(i)}})$. Then, the polynomial $\alpha'_u(x) = \alpha_u(p_l(x)) \pmod{f}$ has the following *direct sum* (or *canonical*) representation in the ring R ,

$$\alpha'_u(x) = \sum_{i=1}^n a_{uj(i)} \chi_i$$

This implies that the polynomial $h'_l(y) = y^t + \alpha'_1 y^{t-1} + \dots + \alpha'_t \in R[y]$ has the *canonical* representation,

$$h'_l(y) = \sum_{i=1}^n \left[\prod_{r \in \tilde{\Delta}_{j(i)}^{(l)}} (y - p_l(\xi_{s_r})) \right] \chi_i \quad (3)$$

Inductively, assume that $g_{l-1}(y)$ has the form,

$$g_{l-1}(y) = \sum_{i=1}^n \left[\prod_{j \in D_i^{(l-1)}} (y - \xi_j) \right] \chi_i$$

Then,

$$\begin{aligned} g_l(y) &= \gcd(g_{l-1}(y), h'_l(p_l(y))) \\ &= \sum_{i=1}^n \gcd \left(\prod_{j \in D_i^{(l-1)}} (y - \xi_j), \prod_{r \in \tilde{\Delta}_{j(i)}^{(l)}} (p_l(y) - p_l(\xi_{s_r})) \right) \chi_i \\ &= \sum_{i=1}^n \left[\prod_{j \in D_i^{(l-1)} \cap \Delta_i^{(l)}} (y - \xi_j) \right] \chi_i \quad (\text{as } r \in \tilde{\Delta}_{j(i)}^{(l)} \Leftrightarrow s_r \in \Delta_i^{(l)}) \end{aligned}$$

Therefore,

$$\begin{aligned} g_l(y) &= \sum_{i=1}^n \left[\prod_{j \in D_i^{(l)}} (y - \xi_j) \right] \chi_i \\ &= \beta_{t'} y^{t'} + \dots + \beta_0 \quad (\text{say}) \end{aligned}$$

where $t' = \max_i (\#D_i^{(l)})$ and $\beta_u \in R$ for $1 \leq u \leq t' \leq \frac{n-1}{2}$. The element $\beta_{t'}$ is not a zero divisor in R if and only if $\#D_1^{(l)} = \dots = \#D_n^{(l)} = t'$. If $t' \leq c$ then a factor of f can be retrieved from $g_l(y)$ in polynomial time using already known methods ([Evd94]). The condition $\#D_i^{(l)} = t'$ for all $i, 1 \leq i \leq t'$, makes the *out* degree of every vertex in G_l equal to t' . However, this may not necessarily imply that the *in* degree of every vertex

in G_l is also t' . Checking for identical *in* degrees of the vertices of G_l is handled in steps (10) – (12) of the algorithm. Consider evaluating the polynomial $g_l(y)$ at a point $y_s \in F_p$.

$$g_l(y_s) = \sum_{i=1}^n \left[\prod_{j \in D_i^{(l)}} (y_s - \xi_j) \right] \chi_i \in R$$

The characteristic polynomial of $g_l(y_s)$ over F_p is,

$$\begin{aligned} c_s(x) &= \prod_{i=1}^n \left(x - \prod_{j \in D_i^{(l)}} (y_s - \xi_j) \right) \\ \Rightarrow -c_s(0) &= \prod_{j=1}^n (y_s - \xi_j)^{k_j} \quad (\text{since } n \text{ is odd}) \end{aligned}$$

where k_j is the *in* degree of vertex v_j in G_l . Let $r(x) = x^{nt'} + r_1 x^{nt'-1} + \dots + r_{nt'} \in F_p[x]$ be a polynomial of degree nt' , such that,

$$r(y_s) = -c_s(0) = \prod_{j=1}^n (y_s - \xi_j)^{k_j}$$

for nt' distinct points $\{y_s\}_{1 \leq s \leq nt'}$ taken from F_p . Since we have assumed that $p > n^2 > \frac{n(n-1)}{2} \geq nt'$, we can solve for the coefficients $r_1, \dots, r_{nt'}$ using any nt' distinct points from F_p . Then,

$$r(x) = \prod_{j=1}^n (x - \xi_j)^{k_j}$$

If $k_j \neq t'$ for some j , then there is an $i = \min\{k_1, \dots, k_n\} < t'$ such that $f^i(x)$ divides $r(x)$ and $\gcd\left(\frac{r(x)}{f^i(x)}, f(x)\right)$ yields a nontrivial factor of $f(x)$. This shows that the graph G_l is regular if the algorithm fails at the l^{th} step. Since $\deg(g_l(y))$ equals the regularity of G_l , hence if the latter quantity is less than c then we can apply Evdokimov's algorithm [Evd94] on $g_l(y)$ and get a non trivial factor of f in polynomial time. ■

Let H_l ($1 \leq l \leq k$) be a digraph with n vertices v_1, \dots, v_n such that there is an edge from v_i to v_j iff $j \in \Delta_i^{(l)}$. Then, graph $G_l = G_{l-1} \cap H_l$ or $G_l = G_{l-1}$ (if $G_{l-1} \cap H_l = \Phi$, where Φ is the null graph with n vertices but no edge). Here \cap denotes the edge intersection of graphs defined on the same set of vertices. (An example in appendix D illustrates the working of algorithm 2.) Algorithm 2 fails to find a proper factor of f in polynomial time if and only if there exists an $l \leq k$ such that G_l is t -regular ($t > c$) and $G_l \cap H_j = G_l$ or Φ for all j , $l < j \leq k$. It is therefore important to choose the polynomials $p_j(\cdot)$ in such a way that very quickly we get a graph H_j with $G_l \cap H_j \neq G_l$ or Φ . We say that a polynomial $p_l(\cdot)$ is good if either H_l is not regular or $G_l \neq G_{l-1}$ ($1 < l \leq k$). We show that, only a few good polynomials are required.

Lemma 3.2 *Algorithm 2 (with a slight modification) requires at most $\lceil \log_2 n \rceil$ good auxiliary polynomials to find a proper factor of f .*

Proof: Consider the following modification of algorithm 2. At step 5 of algorithm 2, for $l > 1$, take $g_l(y)$ to be either $\gcd(g_{l-1}(y), h'_l(p_l(y)))$ or $g_{l-1}(y)/\gcd(g_{l-1}(y), h'_l(p_l(y)))$, whichever has the smaller nonzero degree. Accordingly, we modify the definition of graph G_l . Define the set $\bar{\Delta}_i^{(l)}$ ($1 \leq i \leq n$) as,

$$\bar{\Delta}_i^{(l)} = \{1 \leq j \leq n : j \neq i, \sigma((p_l(\xi_i) - p_l(\xi_j))^2) = (p_l(\xi_i) - p_l(\xi_j))\} = \{1 \leq j \leq n : j \neq i\} - \Delta_i^{(l)}$$

and modify the definition of the sets $D_i^{(l)}$ ($1 \leq i \leq n$) as,

$$\begin{aligned} D_i^{(1)} &= \Delta_i^{(1)} \\ \text{For } l > 1, D_i^{(l)} &= D_i^{(l-1)} \cap \Delta_i^{(l)} \text{ if } g_l(y) = \gcd(g_{l-1}(y), h'_l(p_l(y))) \\ &= D_i^{(l-1)} \cap \bar{\Delta}_i^{(l)} \text{ else if } g_l(y) = g_{l-1}(y)/\gcd(g_{l-1}(y), h'_l(p_l(y))) \end{aligned}$$

As before, an edge (v_i, v_j) is present in G_l iff $j \in D_i^{(l)}$. This modification ensures that, if $g_l(y) \neq g_{l-1}(y)$ has an invertible leading coefficient (i.e if $g_l(y)$ is monic) then the degree of $g_l(y)$ is at most half the degree of $g_{l-1}(y)$. Hence, for every good choice of polynomial $p_l(\cdot)$ if G_{l-1} and G_l are t_{l-1} -regular and t_l -regular, respectively, then $t_l \leq \frac{t_{l-1}}{2}$. Therefore, at most $\lceil \log_2 n \rceil$ good choices of polynomials $p_l(\cdot)$ are required by the algorithm. ■

Theorem 1.1 follows as a corollary to theorem 3.1 and lemma 3.2. As already pointed out in section 1, if only $\epsilon \lceil \log_2 n \rceil$ good auxiliary polynomials are available for some ϵ , $0 < \epsilon \leq 1$, then we obtain a nontrivial factor $g(y)$ of $f'(y)$ with degree at most $\frac{n^{1-\epsilon}}{2}$. If we apply Evdokimov's algorithm on $g(y)$ instead of $f'(y)$, then the maximum dimension of the rings considered is bounded by $n^{\frac{(1-\epsilon)^2}{2} \log n + \epsilon + O(1)}$ instead of $n^{\frac{\log n}{2} + O(1)}$ (as is the case in [Evd94]).

In the following discussion we analyze the performance of algorithm 2 based on uniform random choices of the auxiliary polynomials $p_l(\cdot)$ ($1 < l \leq k$).

Lemma 3.3 *If $p \equiv 3 \pmod{4}$ and $p \geq n^6 2^{2n}$ then about $\frac{(1+o(1))^n}{(\frac{\pi}{2}n)^{\frac{n}{2}}}$ fraction of all completely splitting, square-free polynomials of degree n are square balanced.*

Proof: See appendix C. ■

Corollary 3.1 *If $p \equiv 3 \pmod{4}$, $p > n^6 2^{2n}$ and $p_l(y)$ is a uniformly randomly chosen polynomial of degree $(n-1)$ then the probability that f_l is either not square-free or is a square-free and square balanced polynomial is upper bounded by $\frac{(1+o(1))^n}{(\frac{\pi}{2}n)^{\frac{n}{2}}}$.*

It follows that, for $p \equiv 3 \pmod{4}$ and $p > n^6 2^{2n}$, if the auxiliary polynomials $p_l(\cdot)$'s are uniformly randomly chosen then algorithm 2 works in randomized polynomial time. However, the arguments used in the proof of lemma 3.3 do not immediately apply to the case $p \equiv 1 \pmod{4}$. Therefore, we resort to a more straightforward analysis, although in the process we get a slightly weaker probability bound.

Lemma 3.4 *If G_l ($1 \leq l < k$) is regular and $p_{l+1}(y) \in F_p[y]$ is a uniformly randomly chosen polynomial of degree $(n-1)$ then $G_{l+1} \neq G_l$ with probability at least $1 - \frac{1}{2^{0.9n-2}}$.*

Proof: See appendix C. ■

Thus, if polynomials $p_l(y)$, $1 < l \leq \lceil \log_2 n \rceil$, are randomly chosen, then the probability that f is not factored by algorithm 2 within $\lceil \log_2 n \rceil$ iterations is less than $\frac{\lceil \log_2 n \rceil}{2^{0.9n-2}}$.

4 Conclusion

In this paper, we have extended the square balance test by [Gao01] and showed a direction towards improving the time complexity of the best previously known deterministic factoring algorithms. Using certain auxiliary polynomials, our algorithm attempts to exploit an

inherent asymmetry among the roots of the input polynomial f in order to efficiently find a proper factor. The advantage of using auxiliary polynomials is that, unlike [Evd94], it avoids the need to carry out computations in rings with large dimension, thereby saving overall computation time to a significant extent. Motivated by the stringent symmetry requirement from the roots of f , we pose the following question:

- Is it possible to construct good auxiliary polynomials in deterministic polynomial time?

An affirmative answer to the question will immediately imply that factoring polynomials over finite fields can be done in deterministic polynomial time under ERH.

Acknowledgement

The author would like to thank Manindra Agrawal for many insightful discussions that helped in improving the result.

A Proof of Lemma 3.1

Lemma A.1 *If f_l is not of the form $f_l = \tilde{f}_l^{d_l}$, where \tilde{f}_l is a square-free, square balanced polynomial and $d_l > 0$, then a proper factor of f can be retrieved in polynomial time.*

Proof: By definition, $f_l = \prod_{i=1}^n (x - p_l(\xi_i))$. Define the sets E_i , for $1 \leq i \leq n$, as $E_i = \{1 \leq j \leq n : p_l(\xi_j) = p_l(\xi_i)\}$. Consider the following gcd in the ring $R[y]$,

$$\begin{aligned} g(y) &= gcd(p_l(y) - p_l(X), f(y)) \\ &= \sum_{i=1}^n \left[\prod_{j \in E_i} (y - \xi_j) \right] \chi_i \end{aligned}$$

The leading coefficient of $g(y)$ is a zero-divisor in R , unless $\#E_1 = \dots = \#E_n = d_l$ (say). Therefore, we can assume that,

$$\begin{aligned} f_l &= \prod_{j=1}^{m_l} (x - p_l(\xi_{s_j}))^{d_l} \quad \text{where } p_l(\xi_{s_1}), \dots, p_l(\xi_{s_{m_l}}) \text{ are all distinct and } m_l = \frac{n}{d_l} \\ &= \tilde{f}_l^{d_l} \quad \text{where } \tilde{f}_l = \prod_{j=1}^{m_l} (x - p_l(\xi_{s_j})) \text{ is square-free.} \end{aligned}$$

Moreover, \tilde{f}_l can be obtained by square-freing f_l (using gcd of f_l with its derivative) in polynomial time. If \tilde{f}_l is not square balanced then a proper factor \tilde{g}_l of \tilde{f}_l is returned by algorithm 1. But then,

$$gcd(\tilde{g}_l(p_l(x)), f(x)) = \prod_{j: \tilde{g}_l(p_l(\xi_j))=0} (x - \xi_j)$$

is a proper factor of f . ■

B Review of Evdokimov's Algorithm

Evdokimov [Evd94] proposed the first deterministic sub-exponential time factoring algorithm that works in time $(n^{\frac{1}{2} \log n + c_1} \log p)^{c_2}$ (where c_1 and c_2 are constants), under the assumption of the ERH. We describe this algorithm briefly. It is already known (from [Rón88]) that a nontrivial factor of $f(x)$ can be computed in polynomial time, if $deg(f)$ is even. If $deg(f)$ is odd, consider the ring $R_1 = R = \frac{F_p[x]}{(f(x))}$ and factor $f(y)$ in $R[y]$ as,

$$f(y) = (y - X) \cdot f'(y) \quad \text{where } f'(y) \in R[y] \text{ and } X = x \pmod{f}$$

Now that $deg(f')$ is even, factor $f'(y) \in R[y]$ using a generalization of the result by [Rón88] (see Lemma 8 in [Evd94]). The process either yields a zero-divisor in R or it factors $f'(y)$ into two nontrivial factors $h'(y)$ and $g'(y)$ such that $f'(y) = h'(y) \cdot g'(y)$. If both $h'(y)$ and $g'(y)$ are of odd degree, repeat the above procedure by considering the ring $R_2 = \frac{R[y]}{(h'(y))}$ (assuming $deg(h') < deg(g')$) and expressing $h'(z)$ as,

$$h'(z) = (z - Y) \cdot h''(z) \quad \text{where } h''(z) \in R_2[z] \text{ and } Y = y \pmod{h'}$$

By considering a hierarchy of higher dimension rings over F_p (R_1, R_2 and so on), Evdokimov's algorithm either finds a zero-divisor in R or it constructs a linear factor $(y - \phi(X))$ of $f'(y)$ in $R[y]$. [Evd94] further showed that $\phi(X)$, which defines an *endomorphism* in

R , can in turn be used to find a nontrivial factor of $f(x)$ efficiently (see lemma 9 in [Evd94]). Although, Evdokimov's algorithm works in sub-exponential time, the inherent disadvantage of algorithms using higher dimensional rings over F_p is that, by nature such algorithms incur the cost of operating with elements belonging to these large rings; the cost being polynomial in the dimension of the ring over F_p . In Evdokimov's algorithm the largest ring used is of dimension $n^{\frac{1}{2}(\log n + O(1))}$ over F_p , thereby justifying the complexity term $(n^{\frac{1}{2} \log n + c_1} \log p)^{c_2}$.

C Proofs of Lemma 3.3 and 3.4

Lemma C.1 *If $p = 3 \pmod{4}$ and $p \geq n^6 2^{2n}$ then about $\frac{(1+o(1))^n}{(\frac{\pi}{2}n)^{\frac{n}{2}}}$ fraction of all completely splitting, square-free polynomials of degree n are square balanced.*

Proof: With every completely splitting, square-free polynomial $f = \prod_{i=1}^n (x - a_i)$, we can associate a tournament H on n vertices $\{v_1, \dots, v_n\}$ with the natural correspondence between vertex v_i and root a_i for all i , $1 \leq i \leq n$, such that (v_i, v_j) is an edge in H iff $(a_i - a_j)$ is a quadratic non-residue. Such a tournament is also known as *Paley tournament*. Since $p = 3 \pmod{4}$, f is a square balanced polynomial iff H is a labeled regular tournament on n vertices. We bound the fraction of polynomials that can be associated to a particular labeled tournament.

Let T be a fixed labeled tournament. Suppose that, for some $i > 1$, the elements in $S_{i-1} = \{a_1, \dots, a_{i-1}\}$ are already chosen in a way that is compatible to the subgraph of T induced by the vertices v_1, \dots, v_{i-1} . Let n_i be the number of possible values of a_i such that the edge constraints from v_i to vertices v_1, \dots, v_{i-1} are maintained. Then n_i can be equated as,

$$2^{i-1} \cdot n_i = \sum_{x_i \in F_p^\times \setminus S_{i-1}} \prod_{j=1}^{i-1} (1 + j \chi(x_i - a_j))$$

where χ is the quadratic character and the symbol $+_j$ is $+$ if (v_j, v_i) is an edge in T and $-$ if (v_i, v_j) is an edge in T . By expanding the inner product we get,

$$\begin{aligned} 2^{i-1} \cdot n_i &= \sum_{x_i \in F_p^\times \setminus S_{i-1}} \sum_{0 \leq e_1, \dots, e_{i-1} \leq 1} \text{sign}(e_1, \dots, e_{i-1}) \cdot \chi \left(\prod_{j=1}^{i-1} (x_i - a_j)^{e_j} \right) \\ &= \sum_{0 \leq e_1, \dots, e_{i-1} \leq 1} \text{sign}(e_1, \dots, e_{i-1}) \cdot \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi \left(\prod_{j=1}^{i-1} (x_i - a_j)^{e_j} \right) \end{aligned}$$

The term corresponding to $e_1 = \dots = e_{i-1} = 0$ is $(p - i)$. For any other fixed e_1, \dots, e_{i-1} , the inner sum is of the form,

$$\text{sign}(e_1, \dots, e_{i-1}) \cdot \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi(q(x_i))$$

where $q(x_i) = \prod_{j=1}^{i-1} (x_i - a_j)^{e_j}$ is not a perfect square as a_1, \dots, a_{i-1} are distinct, and $1 \leq \deg(q(x_i)) \leq (i - 1)$. By applying Weil's theorem we get,

$$\begin{aligned} \text{sign}(e_1, \dots, e_{i-1}) \cdot \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi(q(x_i)) &\leq \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi(q(x_i)) \\ &\leq \left| \sum_{x_i \in F_p} \chi(q(x_i)) \right| + i \\ &\leq (i - 2)\sqrt{p} + i \end{aligned}$$

Therefore,

$$\begin{aligned}
2^{i-1} \cdot n_i &\leq (p-i) + (2^{i-1} - 1)((i-2)\sqrt{p} + i) \\
\Rightarrow n_i &\leq \frac{p-i}{2^{i-1}} + (i-2)\sqrt{p} + i \\
\Rightarrow \frac{n_i}{p-i} &\leq \frac{1}{2^{i-1}} \left(1 + \frac{2^{i-1}((i-2)\sqrt{p} + i)}{p-i} \right) \\
&\leq \frac{1}{2^{i-1}} \left(1 + \frac{1}{n^2} \right) \quad \text{if } p \geq n^6 2^{2n}
\end{aligned}$$

And hence,

$$Pr_{a_1, \dots, a_n} \{T \text{ is induced by } \{a_1, \dots, a_n\}\} \leq \frac{e^{\frac{1}{n}}}{2^{\binom{n}{2}}} = \frac{1+o(1)}{2^{\binom{n}{2}}}$$

By a similar argument we get,

$$\begin{aligned}
\text{sign}(e_1, \dots, e_{i-1}) \cdot \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi(q(x_i)) &\geq - \sum_{x_i \in F_p^\times \setminus S_{i-1}} \chi(q(x_i)) \\
&\geq -((i-2)\sqrt{p} + i)
\end{aligned}$$

which implies that,

$$\begin{aligned}
\frac{n_i}{p-i} &\geq \frac{1}{2^{i-1}} \left(1 - \frac{1}{n^2} \right) \quad \text{if } p \geq n^6 2^{2n} \\
\Rightarrow Pr_{a_1, \dots, a_n} \{T \text{ is induced by } \{a_1, \dots, a_n\}\} &\geq \frac{e^{-\frac{1}{n}}}{2^{\binom{n}{2}}} = \frac{1+o(1)}{2^{\binom{n}{2}}} \\
\Rightarrow Pr_{a_1, \dots, a_n} \{T \text{ is induced by } \{a_1, \dots, a_n\}\} &= \frac{1+o(1)}{2^{\binom{n}{2}}}
\end{aligned}$$

The polynomial f is square balanced iff the associated tournament H is regular. The number of regular tournaments on n vertices is given by [Spe74] as,

$$R_n = 2^{\binom{n}{2}} \frac{(1+o(1))^n}{\left(\frac{\pi}{2}n\right)^{\frac{n}{2}}}$$

Therefore,

$$Pr_{a_1, \dots, a_n} \{\text{polynomial } f = \prod_{i=1}^n (x - a_i) \text{ is square balanced}\} \approx \frac{(1+o(1))^n}{\left(\frac{\pi}{2}n\right)^{\frac{n}{2}}}$$

■

Lemma C.2 *If G_l ($1 \leq l < k$) is regular and $p_{l+1}(y) = \sum_{m=1}^{n-1} c_m y^m \in F_p[x]$ is a randomly chosen polynomial of degree $(n-1)$ then $G_{l+1} \neq G_l$ with probability at least $1 - \frac{1}{2^{0.9n-2}}$.*

Proof: Suppose that, G_l is t -regular where $t \geq 5$. Otherwise, if $t = \deg(g_l(y)) < 5$ then we can efficiently solve for a root of $g_l(y)$ (or $f(y)$, since $g_l(y)$ divides $f(y)$) in R using radicals. In the process either a nontrivial endomorphism of R or a zero divisor in R is obtained. In either case we can efficiently retrieve a proper factor of f .

Assume that G_l has c connected components. Surely, $c \leq \frac{n}{2t+1}$ as G_l is t -regular. Consider any connected component G_l^k ($1 \leq k \leq c$) with n_k vertices and T_l^k be a depth-first tree with any particular vertex in G_l^k as the root. Since G_l is a regular digraph,

any connected component is also strongly connected and hence T_l^k is a spanning tree of G_l^k containing n_k vertices with $n_k - 1$ edges. Let the vertices of T_l^k be v_1, \dots, v_{n_k} and the roots of f associated with these vertices be ξ_1, \dots, ξ_{n_k} , respectively. For every edge $e_{ij} = (v_i, v_j)$ in T_l^k , $1 \leq k \leq c$, consider the equation,

$$p_{l+1}(\xi_i) - p_{l+1}(\xi_j) = \sum_{m=1}^{n-1} c_m (\xi_i^m - \xi_j^m) = a_{ij} \quad (4)$$

for a given $a_{ij} \in F_p$ with $\bar{c} = (c_1, \dots, c_{n-1})$ as the variables. Let $p - 1 = 2^e w$, where w is odd. [Gao01] showed that, given a primitive 2^e -th root of unity η , if $a = \eta^u \theta$ where $\theta^w = 1$ then $\sigma(a^2) = a$ iff $u < 2^{e-1}$. We say that two elements $a, b \in F_p$ have the *same character* if, $\sigma(a^2) = a$ if and only if $\sigma(b^2) = b$. For convenience, assume that 0 has the same character as any other non-zero element a iff $\sigma(a^2) = a$.

An edge e_{ij} in G_l is also present in $G_l \cap H_{l+1}$ if and only if $a_{ij} = \eta^u \theta$ with $u > 2^{e-1}$. Therefore, all the trees T_l^k , $1 \leq k \leq c$, are either totally present or totally absent in $G_l \cap H_{l+1}$ iff all a_{ij} 's (corresponding to all the edges of the trees T_l^k 's) have the same character. Writing down the equation (as in (4)) for every edge in every tree T_l^k , $1 \leq k \leq c$, gives a set of $(n - c)$ linear equations in $n - 1$ variables, namely $\bar{c} = \{c_1, \dots, c_{n-1}\}$. Let $M_{n-c, n-1}$ be the coefficient matrix of the set of linear equations. It is not difficult to verify that $\text{rank}(M_{n-c, n-1}) = n - c$. Otherwise, the determinant of the matrix $(\xi_i^j)_{i,j}$, $1 \leq i \leq n$, $0 \leq j \leq n - 1$ is 0, which is not possible since $\xi_i \neq \xi_j$ for $i \neq j$. This means, for every choice of values of the a_{ij} 's we have at most p^{c-1} choices of polynomials $p_{l+1}(\cdot)$ satisfying the linear equations. A polynomial $p_{l+1}(\cdot)$ is a bad choice only if all a_{ij} 's have the same character. This can happen for at most,

$$\left(\frac{p-1}{2}\right)^{n-c} + \left(\frac{p+1}{2}\right)^{n-c} \leq 3 \cdot \left(\frac{p}{2}\right)^{n-c} \quad (\text{assuming } n-1 \leq \frac{p}{2})$$

different choices of the a_{ij} 's. Therefore, the probability that a random choice of $p_{l+1}(\cdot)$ is bad is at most,

$$\text{Pr}_{\bar{c}}\{p_{l+1}(\cdot) \text{ is bad}\} < \frac{p^{c-1} \cdot 3 \cdot \left(\frac{p}{2}\right)^{n-c}}{p^{n-1}} < \frac{1}{2^{n-c-2}}$$

Since G_l is t -regular $c \leq \frac{n}{2t+1}$. Therefore,

$$\text{Pr}_{\bar{c}}\{p_{l+1}(\cdot) \text{ is bad}\} < \frac{1}{2^{n \cdot \left(\frac{2t}{2t+1}\right) - 2}} < \frac{1}{2^{0.9n-2}} \quad \text{assuming } t \geq 5$$

■

D An Example

Example D.1 Let $p = 19 = 3 \pmod{4}$ and $f = f_1 = (x-2)(x-6)(x-9)(x-12)(x-15)$ be the input polynomial. Suppose that the algorithm chooses $p_2(y) = y^2$. Then, $f_2 = (x-4)(x-17)(x-5)(x-11)(x-16)$. Since $p = 3 \pmod{4}$, there is an edge from v_i to v_j in H_1 (resp. H_2) iff $\xi_i - \xi_j$ (resp. $\xi_i^2 - \xi_j^2$) is a quadratic nonresidue. The nonresidues in F_{19} are $\{2, 3, 8, 10, 12, 13, 14, 15, 18\}$. The graphs G_1 , H_2 and G_2 are depicted in figure 1.

Note that, both f_1 and f_2 are square free and square balanced. But, since G_2 is irregular, algorithm 2 finds a proper factor of f at the second iteration.

Figure 1: An example showing the working of Algorithm 2.
