DEMystifying the Border of Depth-3 Algebraic Circuits

PRANJAL DUTTA†, PRATEEK DWIVEDI‡, AND NITIN SAXENA§

Abstract. Border complexity of polynomials plays an integral role in GCT (Geometric complexity theory) approach to $P \neq NP$. It tries to formalize the notion of ‘approximating a polynomial’ via limits (Bürgisser FOCS’01). This opens the question $\mathbf{VP} \neq \mathbf{VNP}$ as the approximation involves exponential precision which may not be efficiently simulable. Recently (Kumar ToCT’20) proved the universal power of the border of top-fanin-2 depth-3 circuits ($\Sigma^2 \Pi^2$). Here we answer some of the related open questions. We show that the border of bounded top-fanin depth-3 circuits ($\Sigma^k \Pi^2$ for constant $k$) is relatively easy—it can be computed by a polynomial size algebraic branching program (ABP). There were hardly any de-bordering results known for prominent models before our result. Moreover, we give the first quasipolynomial-time blackbox identity test for the same. Prior best was in PSPACE (Forbes,Shpilka STOC’18). Also, with more technical work, we extend our results to depth-4. Our de-bordering paradigm is a multi-step process; in short we call it DiDIL—divide, derive, induct, with limit. It ‘almost’ reduces $\Sigma^k \Pi^2$ to special cases of read-once oblivious algebraic branching programs (ROABPs) in any-order.

Key words. approximative, border, depth-3, depth-4, circuits, de-border, derandomize, black-box, PIT, GCT, any-order, ROABP, ABP, VBP, VP, VNP.

1. Introduction: Border Complexity, GCT and Beyond. Algebraic circuit is a natural (& non-uniform) model of polynomial computation, which comprises the vast study of algebraic complexity [118]. We say that a polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$, over a field $\mathbb{F}$ is computable by a circuit of size $s$ and depth $d$ if there exists a directed acyclic graphs of size $s$ (nodes + edges) and depth $d$ such that its leaf nodes are labelled by variables or field constants, internal nodes are labelled with $+$ and $\times$, and the polynomial computed at the root is $f$. Further, if the output of a gate is never re-used then it is a Formula. Any formula can be converted into a layered graph called Algebraic Branching Program (ABP). Various complexity measures can be defined on the computational model to classify polynomials in different complexity classes. For eg. $\mathbf{VP}$ (respectively $\mathbf{VBP}$, respectively $\mathbf{VF}$) is the class of polynomials of polynomial degree, computable by polynomial-sized circuits (respectively ABPs, respectively formulas). Finally, $\mathbf{VNP}$ is the class of polynomials, each of which can be expressed as an exponential-sum of projection of a $\mathbf{VP}$ circuit family. For more details, refer to subsection 2.1 and [113, 87].

The problem of separating algebraic complexity classes has been a central theme of this study. Valiant [118] conjectured that $\mathbf{VBP} \neq \mathbf{VNP}$, and even a stronger $\mathbf{VP} \neq \mathbf{VNP}$, as an algebraic analog of $P$ vs. $NP$ problem. Over the years, an impressive progress has been made towards resolving this, however, the existing tools have not been able to resolve this conclusively. In this light, Mulmuley and Sohoni [92] introduced Geometric Complexity Theory (GCT) program, where they studied

the border (or approximative) complexity, with the aim of approaching Valiant’s conjecture and strengthening it to: $\text{VNP} \nsubseteq \text{VP}$, i.e. (padded) permanent does not lie in the orbit closure of ‘small’ determinants. This notion was already studied in the context of designing matrix multiplication algorithms [115, 17, 18, 36, 83]. The hope, in the GCT program, was to use available tools from algebraic geometry and representation theory, and possibly settle the question once and for all. This also gave a natural reason to understand the relationship between $\text{VP}$ and $\text{VNP}$ (or $\text{VBP}$ and $\text{VBV}$).

Outside $\text{VP}$ vs. $\text{VNP}$ implication, GCT has deep connections with computational invariant theory [50, 94, 53, 29, 70], algebraic natural proofs [57, 21, 34, 80], lower bounds [30, 56, 83], optimization [8, 28] and many more. We refer to [31, Sec. 9] and [94, 91] for expository references.

The simplest notion of the approximative closure comes from the following definition [25, 26]: a polynomial $f(x) \in \mathbb{F}[x_1, \ldots, x_n]$ is approximated by $g(x, \varepsilon) \in \mathbb{F}(\varepsilon)[x]$ if there exists a $Q(x, \varepsilon) \in \mathbb{F}[\varepsilon][x]$ such that $g = f + \varepsilon Q$. We can also think analytically (in $\mathbb{F} = \mathbb{R}$ Euclidean topology) that $\lim_{\varepsilon \to 0} g = f$. If $g$ belongs to a circuit class $C$ (over $\mathbb{F}(\varepsilon)$, i.e. any arbitrary $\varepsilon$-power is allowed as ‘cost-free’ constants), then we say that $f \in C$, the approximative closure of $C$. Further, one could also think of the closure as Zariski closure (algebraic definition over any $\mathbb{F}$), i.e. taking the closure of the set of polynomials (considered as points) of $C$. Let $\mathcal{I}$ be the smallest (annihilating) ideal whose zeros cover $\{\text{coefficient-vector of } g \mid g \in C\}$; then put in $\overline{C}$ each polynomial $f$ with coefficient-vector being a zero of $\mathcal{I}$. Interestingly, all these notions are equivalent over the algebraically closed field $\mathbb{C}$ [95, §2.C].

The size of the circuit computing $g$ defines the approximative (or border) complexity of $f$, denoted $\overline{\text{size}}(f)$; evidently, $\overline{\text{size}}(f) \leq \text{size}(f)$. Due to the possible $1/\varepsilon^M$ terms in the circuit computing $g$, evaluating it at $\varepsilon = 0$ may not be necessarily valid (though limit exists). Hence, given $f \in \overline{C}$, does not immediately reveal anything about the exact complexity of $f$. Since $g(x, \varepsilon) = f(x) + \varepsilon \cdot Q(x, \varepsilon)$, we could extract the coefficient of $\varepsilon^0$ from $g$ using standard interpolation trick, by setting random $\varepsilon$-values from $\mathbb{F}$. However, the trivial bound on the circuit size of $f$ would depend on the degree $M$ of $\varepsilon$, which could provably be exponential in the size of the circuit computing $g$, i.e. $\overline{\text{size}}(f) \leq \text{size}(f) \leq \exp(\overline{\text{size}}(f))$ [25, Thm. 5.7].

1.1. De-bordering: The upper bound results. The major focus of this paper is to address the power of approximation in the restricted circuit classes. Given a polynomial $f \in \overline{C}$, for an interesting class $C$, we want to upper bound the exact complexity of $f$ (we call it ‘de-bordering’). If $C = \overline{C}$, then $C$ is said to be closed under approximation: Eg. 1) $\Sigma \Pi$, the sparse polynomials (with complexity measure being sparsity), 2) Monotone ABPs [22], and 3) ROABP (read-once ABP) respectively ARO (any-order ROABP), with measure being the width. ARO is an ABP with a natural restriction on the use of variables per layer; for definition and a formal proof, see Theorem 2.8 and Theorem 2.23.

Why care about upper bounds? One of the fundamental questions in the GCT paradigm is whether $\text{VNP} \nsubseteq \text{VP}$ [91, 58]. Confirmation or refutation of this question has multiple consequences, both in the algebraic complexity and at the frontier of algebraic geometry. If $\text{VP} = \text{VNP}$, then any proof of $\text{VP} \neq \text{VNP}$ will in fact also show that $\text{VNP} \nsubseteq \overline{\text{VP}}$, as conjectured in [94]; however a refutation would imply that any realistic approach to the $\text{VP}$ vs. $\text{VNP}$ conjecture would even have to separate the permanent from the families in $\overline{\text{VP}} \setminus \text{VP}$ (and for this, one needs a far better understanding than the current state of the art).

The other significance of the upper bound result arises from the flip [90, 94]...
whose basic idea in a nutshell is to understand the theory of upper bounds first, and
then use this theory to prove lower bounds later. Taking this further to the realm
of algorithms: showing de-bordering results, for even restricted classes (e.g. depth-3,
small-width ABPs), could have potential identity testing implications. For details,
see subsection 1.2.

De-bordering results in GCT are in a very nascent stage; for example, the bound-
ary of $3 \times 3$ determinants was only recently understood [69]. Note that here both the
number of variables $n$ and the degree $d$ are constant. In this work, however, we target
polynomial families with both $n$ and $d$ unbounded. So getting exact results about
such border models is highly nontrivial considering the current state of the art.

De-bordering small-width ABPs. The exponential degree dependence of $\varepsilon$ [25, 26]
suggests us to look for separation of restricted complexity classes or try to upper bound
them by some other means. In [24], the authors showed that $\mathbf{VBP}_2 \subseteq \mathbf{VF} = \mathbf{VF}$ ;
here $\mathbf{VBP}_2$ denotes the class of polynomials computed by width-2 ABP. Surprisingly,
we also know that $\mathbf{VBP}_2 \subseteq \mathbf{VP} = \mathbf{VP}_3$ [13, 9]. Very recently, [22] showed polynomial
gap between ABPs and border-ABPs, in the trace model, for noncommutative and
also for commutative monotone settings (along with $\mathbf{VQP} \neq \mathbf{VNP}$).

Quest for de-bordering depth-3 circuits. Outside such ABP results and depth-
2 circuits, we understand very little about the border of other important models.
Thus, it is natural to ask the same for depth-3 circuits, plausibly starting with depth-
3 diagonal circuits $(\Sigma \wedge \Sigma)$, i.e. polynomials of the form $\sum_{i \in [s]} c_i \cdot \ell_i^d$, where $\ell_i$ are
linear polynomials. Interestingly, the relation between warping rank (minimum $s$ to
compute $f$) and border-waring rank (minimum $s$, to approximate $f$) has been studied
in mathematics since ages [116, 23, 15, 54], yet it is not clear whether the measures
are polynomially related or not. However, we point out that $\Sigma \wedge \Sigma$ has a small ARO;
this follows from the fact that $\Sigma \wedge \Sigma$ has small ARO by duality trick [106], and ARO
is closed under approximation [96, 46]; for details see Theorem 2.24.

This pushes us further to study depth-3 circuits $\Sigma[k] \Pi[d] \Sigma$; these circuits compute
polynomials of the form $f = \sum_{i \in [k]} \prod_{j \in [d]} \ell_{ij}$ where $\ell_{ij}$ are linear polynomials. This
model with bounded fanin has been a source of great interest for derandomization
[42, 75, 72, 109, 6]. In a recent twist, Kumar [79] showed that border depth-3 fanin-2
circuits are ‘universally’ expressive; i.e. $\Sigma[2] \Pi[3] \Sigma$ over $\mathbb{C}$ can approximate any ho-

geneous $d$-degree, $n$-variate polynomial; though his expression requires an exceedingly
large $D = \exp(n, d)$.

Our upper bound results. The universality result of border depth-3 fanin-2 circuits
makes it imperative to study $\Sigma[2] \Pi[3] \Sigma$, for $d = \text{poly}(n)$ and understand its computa-
tional power. To start with, are polynomials in this class even ‘explicit’ (i.e. the
coefficients are efficiently computable)? If yes, is $\Sigma[2] \Pi[3] \Sigma \subseteq \mathbf{VNP}$? (See [58, 44] for
more general questions in the same spirit.) To our surprise, we show that the class is
very explicit; in fact every polynomial in this class has a small ABP. The statement
and its proof is first of its kind which eventually uses analytic approach and ‘reduces’
the $\Pi$-gate to $\wedge$-gate. We remark that it does not reveal the polynomial dependence
on the $\varepsilon$-degree. However, this positive result could be thought as a baby step towards
$\mathbf{VF} = \mathbf{VP}$. We assume the field $\mathbb{F}$ characteristic to be $= 0$, or large enough. For a
detailed statement, see Theorem 3.2.

Theorem 1.1 (De-bordering depth-3 circuits). For any constant $k$, $\Sigma[k] \Pi[3] \Sigma \subseteq
\mathbf{VBP}$, i.e. any polynomial in the border of constant top-fanin size-$s$ depth-3 circuits,
can also be computed by a poly(s)-size algebraic branching program (ABP).
Remarks. 1. When \( k = 1 \), it is easy to show that \( \Pi \Sigma = \Pi \Sigma [24, \text{Prop. A.12}] \) (see Theorem 2.22).

2. The size of the ABP turns out to be \( s^{\exp(k)} \). It is an interesting open question whether \( f \in \Sigma[k] \Pi \Sigma \) has a subexponential ABP when \( k = \Theta(\log s) \).

3. \( \Sigma[k] \Pi \Sigma \) is the orbit closure of \( k \)-sparse polynomials [88, Thm. 1.31]. Separating the orbit and its closure of certain classes is the key difficulty in GCT. Theorem 1.1 is one of the first such results to demystify orbit closures (of constant-sparse polynomials).

Extending to depth-4. Once we have dealt with depth-3 circuits, it is natural to ask the same for constant top-fanin depth-4 circuits. Polynomials computed by \( \Sigma[k] \Pi \Sigma \Pi[\delta] \) circuits are of the form \( f = \sum_{i \in [k]} \prod_{j} g_{ij} \) where \( \deg(g_{ij}) \leq \delta \). Unfortunately, our technique cannot be generalised to this model, primarily due to the inability to de-border \( \Sigma \land \Sigma \Pi[\delta] \). However, when the bottom \( \Pi \) is replaced by \( \land \), we can show \( \Sigma[k] \Pi \Sigma \land \subseteq \text{VBP} \); we sketch the proof in Theorem 5.1.

1.2. Derandomizing the border: The blackbox PITs. Polynomial Identity Testing (PIT) is one of the fundamental decision problems in complexity theory. The Polynomial Identity Lemma [99, 37, 120, 111] gives an efficient randomized algorithm to test the zerones of a given polynomial, even in the blackbox settings (known as Blackbox PIT), where we are not allowed to see the internal structure of the model (unlike the 'whitebox' setting), but evaluations at points are allowed. It is still an open problem to derandomize blackbox PIT. Designing a deterministic blackbox PIT algorithm for a circuit class is equivalent to finding a set of points such that for every nonzero circuit, the set contains a point where it evaluates to a nonzero value [47, Sec. 3.2]. Such a set is called hitting set.

A trivial explicit hitting set for a class of degree \( d \) polynomial of size \( O(d^n) \) can be obtained using the Polynomial Identity Lemma. Heintz and Schnorr [68] showed that \( \text{poly}(s,n,d) \) size hitting set exists for \( d \)-degree, \( n \)-variate polynomials computed (as well as approximated) by circuits of size \( s \). However, the real challenge is to efficiently obtain such an explicit set.

Constructing small size explicit hitting set for \( \text{VP} \) is a long standing open problem in algebraic complexity theory, with numerous algorithmic applications in graph theory [86, 93, 45], factoring [78, 40], cryptography [5], and hardness vs randomness results [68, 97, 1, 71, 43, 41]. Moreover, a long line of depth reduction results [119, 7, 117, 64] and the bootstrapping phenomenon [3, 82, 61, 10] has justified the interest in hitting set construction for restricted classes; e.g. depth 3 [42, 75, 109, 6], depth 4 [51, 12, 48, 112, 100, 101, 38], ROABPs [4, 67, 51, 60, 19] and log-variate depth-3 diagonal circuits [49]. We refer to [113, 107, 81] for expositions.

PIT in the border. In this paper we address the question of constructing hitting set for restrictive border circuits. \( \mathcal{H} \) is a hitting set for a class \( \mathcal{C} \), if \( g(x, \varepsilon) \in \mathcal{C}[\varepsilon(x)] \), approximates a non-zero polynomial \( f(x) \in \mathcal{C} \), then \( \exists a \in \mathcal{H} \) such that \( g(a, \varepsilon) \notin \varepsilon \cdot \mathcal{F}[\varepsilon] \), i.e. \( f(a) \neq 0 \). Note that, as \( \mathcal{H} \) will also ‘hit’ polynomials of class \( \mathcal{C} \), construction of hitting set for the border classes (we call it ‘border PIT’) is a natural and possibly a different avenue to derandomize PIT. Here, we emphasize that \( a \in \mathbb{F}^n \) such that \( g(a, \varepsilon) \neq 0 \), may not hit the limit polynomial \( f \) since \( g(a, \varepsilon) \) might still lie in \( \varepsilon \cdot \mathcal{F}[\varepsilon] \); because \( f \) could have really high complexity compared to \( g \). Intrinsically, this property makes it harder to construct an explicit hitting set for \( \text{VP} \).

We also remark that there is no ‘whitebox’ setting in the border and thus we cannot really talk about ‘\( t \)-time algorithm’; rather we would only be using the term
‘\(t\)-time hitting set’, since the given circuit after evaluating on \(a \in \mathbb{F}^n\), may require arbitrarily high-precision in \(\mathbb{F}(\varepsilon)\).

Prior known border PITs. Mulmuley [91] asked the question of constructing an efficient hitting set for \(\mathbb{V}\). Forbes and Shpilka [52] gave a PSPACE algorithm over the field \(\mathbb{C}\). In [62], the authors extended this result to any field. A very few better hitting set constructions are known for the restricted border classes, eg. poly-time hitting set for \(\Sigma^k \Pi \Sigma \subseteq \mathbb{ARO} \subseteq \mathbb{ROABP}\) [51, 4, 67] and poly-time hitting set for the border of a restricted sum of log-variate ROABPs [19].

Why care about border PIT? PIT for \(\mathbb{V}\) has a lot of applications in the context of borderline geometry and computational complexity, as observed by Mulmuley [91]. For eg. Noether’s Normalization Lemma (NNL); it is a fundamental result in algebraic geometry where the computational problem of constructing explicit normalization map reduces to constructing small size hitting set of \(\mathbb{V}\) [91, 50]. Close connection between certain formulation of derandomization of NNL, and the problem of showing explicit circuit lower bounds is also known [91, 89].

The second motivation comes from the hope to find an explicit ‘robust’ hitting set for \(\mathbb{V}\) [52]; this is a hitting set \(H\) such that after an adequate normalization, there will be a point in \(H\) on which \(f\) evaluates to (say) 1. This notion overcomes the discrepancy between a hitting set for \(\mathbb{V}\) and a hitting set for \(\mathbb{V}\) [52, 88]. We know that small robust hitting set exists [32], but an explicit PSPACE construction was given in [52]. It is not at all clear whether the efficient hitting sets known for restricted depth-3 circuits are robust or not.

Our border PIT results. We continue our study on \(\Sigma^k \Pi \Sigma\) and ask for a better than PSPACE constructible hitting set. Already a polynomial-time hitting set is known for \(\Sigma^k \Pi \Sigma\) [108, 109, 6]. But, the border class seems to be more powerful, and the known hitting sets seem to fail. However, using our structural understanding and the analytic DiDIL technique, we are able to quasi-derandomize the class completely. For the detailed statement, see Theorem 4.1.

THEOREM 1.2 (Quasi-derandomizing depth-3). There exists an explicit quasi-polynomial time \((s^{O((\log s) \log \log s)})\) hitting set for \(\Sigma^k \Pi \Sigma\)-circuits of size \(s\) and constant \(k\).

Remarks. 1. For \(k = 1\), as \(\Pi \Sigma = \Pi \Sigma\), there is an explicit polynomial-time hitting set.

2. Our technique necessarily blows up the size to \(s^{\exp(k) \cdot \log \log s}\). Therefore, it would be interesting to design a subexponential time algorithm when \(k = \Theta(\log s)\); or poly-time for \(k = O(1)\).

3. We can not directly use the de-bordering result of Theorem 1.1 and try to find efficient hitting set, as we do not know explicit good hitting set for general ABPs.

4. One can extend this technique to construct quasi-polynomial time hitting set for depth-4 classes: \(\Sigma^k \Pi \Sigma \Lambda\) and \(\Sigma^k \Pi \Sigma \Pi \delta\), when \(k\) and \(\delta\) are constants. For details, see section 6.

The log-variate regime. In recent developments [3, 82, 61, 41] low-variate polynomials, even in highly restricted models, have gained a lot of clout for their general implications in the context of derandomization and hardness results. A slightly non-trivial hitting set for trivariate \(\Sigma \Pi \Sigma \Lambda\)-circuits [3] would in fact imply quasi-efficient PIT for general circuits (optimized to poly-time in [61] with a hardness hypothesis). This motivation has pushed researchers to work on log-variate regime and design efficient PITs. In [49], the authors showed a \(\mathrm{poly}(s)\)-time blackbox identity test for
\[ n = O(\log s) \text{ variate size-} s \text{ circuits that have } \text{poly}(s)\text{-dimensional partial derivative} \]

space; eg. log-variate depth-3 diagonal circuits. Very recently, Bisht and Saxena [19]
gave the first poly(s)-time blackbox PIT for sum of constant-many, size- \( s \), \( O(\log s) \)-variate constant-width ROABPs (and its border).

We remark that non-trivial border-PIT in the low-variate bootstraps to non-trivial
PIT for \( \mathbf{VP} \) as well [3, 61]. Motivated thus, we try to derandomize log-variate \( \Sigma^{[k]}\Pi^{[s]} \)-circuits. Unfortunately, direct application of Theorem 1.2 fails to give a polynomial-
time PIT. Surprisingly, adapting techniques from [49] to extend the existing result
(Theorem 4.3), combined with our DiDIL technique, we prove the following. For
details, see Theorem 4.4.

**Theorem 1.3 (Derandomizing log-variate depth-3).** There exists an explicit
poly(s)-time hitting set for \( n = O(\log s) \) variate, size- \( s \), \( \Sigma^{[k]}\Pi^{[s]} \) circuits, for constant
\( k \).

**1.3. Limitation of standard techniques.** In this section, we briefly discuss
about the standard techniques for both the upper bounds and PITs, in the border
sense, and point out why they fail to yield our results.

**Why known upper bound techniques fail?** One of the most obvious way to
de-border restricted classes is to essentially show a polynomial \( \varepsilon \)-degree bound and
interpolate. In general, the bound is known to be exponential [26, Thm. 5.7] which
crucially uses [84, Prop. 1]. This proposition essentially shows the existence of an
irreducible curve \( C \) whose degree is bounded in terms of the degree of the affine variety,
that we are interested in. The degree is in general exponentially upper bounded by
the size [27, Thm. 8.48]. Unless and until, one improves these bounds for varieties
induced by specific models (which seems hard), one should not expect to improve the
\( \varepsilon \)-degree bound, and thus interpolation trick seems useless.

As mentioned before, \( \Sigma^{[s]}\Pi^{[s]} \) circuits could be de-bordered using the duality trick
[106] (see Theorem 2.16) to make it an \( \overline{\text{ARO}} \) and finally using Nisan’s characterization
giving \( \text{ARO} = \text{ARO} \) [96, 46, 66] (Theorem 2.23). But this trick is directly inapplicable
to our models with the \( \Pi \)-gate, due to large warping rank & ROABP-width, as one
could expect \( 2^{\frac{\varepsilon}{\text{depth}}} \)-blowup in the top fanin while converting \( \Pi \)-gate to \( \land \). We also remark
that the duality trick was made field independent in [47, Lemma 8.6.4]. In fact,
very recently, [20, Theorem 4.3] gave an improved duality trick with no size blowup,
independent of degree and number of variables.

Moreover, all the non-trivial current upper bound methods, for limit, seem to need
an auxiliary linear space, which even for \( \Sigma^{[2]}\Pi^{[s]} \) is not clear, due to the possibility
of heavy cancellation of \( \varepsilon \)-powers. To elaborate, one of the major bottleneck is that
individually \( \lim_{\varepsilon \to 0} T_i \), for \( i \in [2] \) **may not exist**, however, \( \lim_{\varepsilon \to 0}(T_1 + T_2) \) does exist,
where \( T_i \in \Pi^{[s]} \) (over \( \mathbb{F}(\varepsilon)[x] \)). For eg. \( T_1 := \varepsilon^{-1}(x + \varepsilon^2 y) y \) and \( T_2 := -\varepsilon^{-1}(y + \varepsilon x)x \).
No generic tool is available to ‘capture’ such cancellations, and may even suggest a
non-linear algebraic approach to tackle the problem.

Furthermore, [102] explicitly classified certain factor polynomials to solve non-
border \( \Sigma^{[2]}\Pi^{[s]} \land \) PIT. This factoring-based idea seems to fail miserably when we
study factoring mod \( \langle \varepsilon \rangle \): in that case, we get non-unique, usually exponentially-
many, factorizations. For eg. \( a^2 \equiv (x - a \cdot \varepsilon^{M/2}) \cdot (x + a \cdot \varepsilon^{M/2}) \mod \langle \varepsilon \rangle \); for
all \( a \in \mathbb{F} \). In this case, there are, in fact, infinitely many factorizations. Moreover,
\( \lim_{\varepsilon \to 0} 1/\varepsilon^M \cdot (a^2 - (x - a \cdot \varepsilon^{M/2}) \cdot (x + a \cdot \varepsilon^{M/2})) = a^2 \). Therefore, infinitely many
factorizations may give infinitely many limits. To top it all, Kumar’s result [79] hinted
a possible hardness of border-depth-3 (top-fanin-2). In that sense, ours is a very non-
linear algebraic proof for restricted models which successfully opens up a possibility
of finding non-representation-theoretic, and elementary, upper bounds.

Why known PIT techniques fail? Once we understand $\Sigma^{[k]}\Pi\Sigma$, it is natural
to look for efficient derandomization. However, as we do not know efficient PIT for
ABPs, known techniques would not yield an efficient PIT for the same. Further,
in a nutshell—1) limited (almost non-existent) understanding of linear/algebraic de-
pendence under limit, 2) exponential upper bound on $\epsilon$, and 3) not-good-enough
understanding of restricted border classes make it really hard to come up with an
efficient hitting set. We elaborate these points below.

Dvir and Shpilka [42] gave a rank-based approach to design the first quasi-poly-
nomial time algorithm for $\Sigma^{[k]}\Pi\Sigma$. A series of works [74, 108, 109, 110] finally gave
a $s^{O(k)}$-time algorithm for the same. Their techniques depend on either generaliz-
ing Chinese remaindering (CR) via ideal-matching or certifying paths, or via efficient
variable-reduction, to obtain a good enough rank-bound on the multiplication ($\Pi\Sigma$)
terms. Most of these approaches required a linear space, but possibility of exponen-
tial $\epsilon$-powers and non-trivial cancellations make these methods fail miserably in the
limit. Similar obstructions also hold for [88, 103, 16] which give efficient hitting sets
for the orbit of sparse polynomials (which is in fact dense in $\Sigma\Pi\Sigma$). In particular,
Medini and Shpilka [88] gave PIT for the orbits of variable disjoint monomials (see
[88, Defn. 1.29]), under the affine group, but not the closure of it. Thus, they do not
even give a subexponential PIT for $\Sigma^{[2]}\Pi\Sigma$.

Recently, Guo [59] gave a $s^{k}$-time PIT, for non-SG (Sylvester-Gallai) $\Sigma^{[k]}\Pi\Sigma\Pi^{[k]}$
circuits, by constructing explicit variety evasive subspace families; but to apply this
idea to border PIT, one has to devise a radical-ideal based PIT idea. Currently, this
does not work in the border, as $\epsilon \ mod \ \langle \epsilon^M \rangle$ has an exponentially high nilpotency.
Since radical($\epsilon^M$) = $\langle \epsilon \rangle$, it 'kills' the necessary information unless we can show a
polynomial upper bound on $M$.

Finally, [6] came up with faithful map by using Jacobian + certifying path tech-
nique, which is more about algebraic rank rather than linear-rank. However, it is not
at all clear how it behaves wrt lim$_{\epsilon \to 0}$(). For eg. $f_1 = x_1 + \epsilon^M \cdot x_2$, and $f_2 = x_1$, where
$M$ is arbitrary large. Note that the underlying Jacobian $J(f_1, f_2) = \epsilon^M$ is nonzero;
but it flips to zero in the limit. This makes the whole Jacobian machinery collapse
in the border setting; as it cannot possibly give a variable reduction for the border
model. (Eg, one needs to keep both $x_1$ and $x_2$ above.)

Very recently, [38] gave a quasipolynomial time hitting set for exact $\Sigma^{[k]}\Pi\Sigma\land$
and $\Sigma^{[k]}\Pi\Sigma\Pi^{[k]}$ circuits, when $k$ and $\delta$ are constant. This result is dependent on the
Jacobian technique which fails under taking limit, as mentioned above. However, a
polynomial-time whitebox PIT for $\Sigma^{[k]}\Pi\Sigma\land$ circuits was shown using DiDi-technique
(30) (Divide, Derive and Induct). This cannot be directly used because there was no $\epsilon$
(i.e. without limit) and $\Sigma^{[k]}\Pi\Sigma\land$ has only blackbox access. Further, Theorem 1.1 gives
an ABP, where DiDi-technique cannot be directly applied. Therefore, our DiDi-
technique can be thought of as a strict generalization of the DiDi-technique, first
introduced in [38], which now applies to uncharted borders.

In a recent breakthrough result, Limaye, Srinivasan and Tavenas [85] showed
the first superpolynomial lower bound for constant-depth circuits. Their lower bound
result, together with the ‘hardness vs randomness’ tradeoff result of [35] gives the first
deterministic subexponential-time blackbox PIT algorithm for general constant-depth
circuits. Interestingly, these methods can be adapted in the border setting as well [11].
However, compared to their algorithms, our hitting sets are significantly faster!
1.4. Main tools and a brief road-map. In this section, we sketch the proof of
Theorems 1.1-1.3. The proofs are analytic, based on induction on the top fan-in and
rely on a common high level picture. They use logarithmic derivative, and its power-
series expansion; we call the unifying technique as DiDiL (Di = Divide, D=Derive, I
= Induct, L = Limit). We essentially reduce to the well-known ‘wedge’ models (as
fractions, with unbounded top-fanin) and then ‘interpolate’ it (for Theorem 1.1) or
deduce directly about its nonzeroness (Theorem 1.2-1.3).

Basic tools and notations. The analytic tool that we use, appears in algebra (&
complexity theory) through the ring of formal power series $R[[x_1, \ldots, x_n]]$ (in short
$R[[x]]$), see [98, 40, 114]. One of the advantages of the ring $R[[x]]$ emerges from
the following inverse identity: $(1 - x_1)^{-1} = \sum_{i\geq 0} x_1^i$, which does not make sense
in $R[x]$, but is available now. Lastly, the logarithmic derivative operator $d\log_y(f) =
(\partial_y f)/f$ plays a very crucial role in ‘linearizing’ the product gate, since $d\log_y(f \cdot g) =
\partial_y(f/g)(fg) = (f \cdot \partial_y g + g \cdot \partial_y f)/(fg) = d\log_y(f) + d\log_y(g)$. Essentially, this
operator enables us to use power-series expansion and converts the $\prod$-gate to $\wedge$.

The road-map. The base case when the top fan-in $k = 1$, i.e., we have a single
product of affine linear forms, and we are interested in its border. It is not hard
to see that the polynomial in the border is also just a product of appropriate affine
forms; for details refer to section 3). Now, suppose we have a depth-3 circuit of top
fan-in 2, $g(x, \varepsilon) = T_1 + T_2$, where each $T_i$ is a product of affine linear forms. The goal
is to somehow reduce this to the case of single summand. Before moving forward,
we remark that some ideas described below, directly, can even be formally incorrect!
Nonetheless, this sketch is “morally” correct and, the eventual road-map insinuates
the strength of the DiDiL-technique.

For simplicity, let us assume that each linear form has a non-zero constant term
(for instance by a random translation of the variables). Moreover, every variable $x_i$ is
replaced by $x_i \cdot z$ for a new variable $z$; this variable $z$ is the ‘degree counter’ that helps
to keep track of the degree of the polynomials involved. Now, dividing both sides by
$T_1$, we get $g/T_1 = 1 + T_2/T_1$, and taking derivatives with respect to the variable $z$, we
get $\partial_z(g/T_1) = \partial_z(T_2/T_1)$. This has reduced the number of summands on the right
hand side to 1, although each summand has become more complicated now, and we
have no control on what happens as $\varepsilon \rightarrow 0$.

Since $T_1$ is invertible in the power series ring in $z$, $T_2/T_1$ is well defined as
well. Moreover, $\lim_{z \rightarrow 0} T_1$ exists (well not really, but formally a proper $\varepsilon$-scaling
of it does, which suffices since derivative wrt $z$ does not affect the $\varepsilon$-scaling!) and is
non-zero. From this it follows that after some truncation wrt high degree $z$ monomials,
$\lim_{z \rightarrow 0} \partial_z(T_2/T_1)$ exists and has a nice relation to the original limit of $g$; see Claim 3.4!

Lastly, and crucially, $\partial_z(T_2/T_1) \mod z^d = (T_2/T_1) \cdot d\log(T_2/T_1) \mod z^d$ can be
computed by a not-too-complicated circuit structure. Interestingly, the circuit form is
closed under this operation of dividing, taking derivatives and taking limits! Note that
the $d\log$ operator distributes the product gate into summation giving $d\log(T_2/T_1) =
\sum d\log(\Sigma)$, where $\Sigma$ denotes linear polynomials, and we observe that $d\log(\Sigma) = \Sigma/\Sigma \in
\Sigma \wedge \Sigma$, the depth-3 powering circuits, over some ‘nice’ ring. The idea is to expand $1/\ell$,
where $\ell$ is a linear polynomial, as sum of powers of linear terms using the inverse
identity:

$$1/(1 - a \cdot z) \equiv 1 + a \cdot z + \cdots + a^{d-1} \cdot z^{d-1} \mod z^d.$$

When there is a single remaining summand, the border of the more general struc-
ture is easy-to-compute, and can be shown to have an algebraic branching program of
not too large size. For details, we refer to Claim 3.6. For a constant $k$ (and even general bounded depth-4 circuits), the above idea can be extended with some additional clever division and computation.

The PIT results also have a similar high level strategy, although there are additional technical difficulties which need some care at every stage. At the core, the idea is really “primal” and depends on the following: If a bivariate polynomial $G(X, Z) \neq 0$, then either its derivative $\partial_Z G(X, Z) \neq 0$, or its constant-term $G(X, 0) \neq 0$ (note: $G(X, 0) = G \mod Z$). So, if $G(a, 0) \neq 0$ or $\partial_Z G(b, Z) \neq 0$, then the union-set $\{a, b\}$ hits $G(X, Z)$, i.e. either $G(a, Z) \neq 0$ or $G(b, Z) \neq 0$.

2. Preliminaries. In this section, we describe some of the assumptions and notations used throughout the paper.

Notation. Denote $[n] = \{1, \ldots, n\}$, and $x = (x_1, \ldots, x_n)$. For, $a = (a_1, \ldots, a_n), b = (b_1, \ldots, b_n) \in \mathbb{F}^n$, and a variable $t$, we denote $a + t \cdot b := (a_1 + tb_1, \ldots, a_n + tb_n)$.

We also use $\mathbb{F}[x]$, to denote the ring of formal power series over $\mathbb{F}$. Formally, $f = \sum_{i \geq 0} c_i x^i$, with $c_i \in \mathbb{F}$, is an element in $\mathbb{F}[x]$. Further, $\mathbb{F}(x)$ denotes the function field, where the elements are of the form $f/g$, where $f, g \in \mathbb{F}[x]$ ($g \neq 0$).

Logarithmic derivative. Over a ring $R$ and a variable $y$, the logarithmic derivative $d\log_y : R[y] \to R(y)$ is defined as $d\log_y(f) := \partial_y f/f$; here $\partial_y$ denotes the partial derivative wrt variable $y$. One important property of $d\log$ is that it is additive over a product as $d\log_y(f \cdot g) = \partial_y (fg)/(fg) = (f \cdot \partial_y g + g \cdot \partial_y f)/(fg) = d\log_y(f) + d\log_y(g)$.

Valuation. Valuation is a map $\text{val}_y : R[y] \to \mathbb{Z}_{\geq 0}$, over a ring $R$, such that $\text{val}_y(\cdot)$ is defined to be the maximum power of $y$ dividing the element. It can be easily extended to fraction field $R(y)$, by defining $\text{val}_y(p/q) := \text{val}_y(p) - \text{val}_y(q)$; where it can be negative.

Field. We denote the underlying field as $\mathbb{F}$ and assume that it is of characteristic 0 (e.g. $\mathbb{Q}, \mathbb{Q}_p$). All our results hold for other fields (e.g. $\mathbb{F}_p$) of large characteristic $p$.

Approximative closure. For an algebraic complexity class $\mathcal{C}$, the approximation is defined as follows [24, Def. 2.1].

**Definition 2.1 (Approximative closure of a class).** Let $\mathcal{C}_\mathbb{F}$ be a class of polynomials defined over a field $\mathbb{F}$. Then, $f(x) \in \mathbb{F}[x_1, \ldots, x_n]$ is said to be in Approximative Closure $\mathcal{C}$ if and only if there exists polynomial $Q \in \mathbb{F}[\varepsilon, x]$ such that $\mathcal{C}_\mathbb{F} \ni g(x, \varepsilon) = f(x) + \varepsilon \cdot Q(x, \varepsilon)$.

Cone-size of monomials. For a monomial $x^a$, the cone of $x^a$ is the set of all sub-monomials of $x^a$. The cardinality of this set is called cone-size of $x^a$. It equals $\prod_{i \in [n]} (a_i + 1)$, where $a = (a_1, \ldots, a_n)$. We will denote $cs(m)$, as the cone-size of the monomial $m$.

Here is an important lemma, originally from [47, Corollary 4.14], which shows that small partial derivative space implies existence of small cone-size monomial. For a detailed proof, we refer to [55, Lemma 2.3.15]

**Theorem 2.2 (Cone-size concentration).** Let $\mathbb{F}$ be a field of characteristic 0 or greater than $d$. Let $\mathcal{P}$ be a set of $n$-variate $d$-degree polynomials over $\mathbb{F}$ such that for all $P \in \mathcal{P}$, the dimension of the partial derivative space of $P$ is at most $k$. Then every nonzero $P \in \mathcal{P}$ has a cone-size-$k$ monomial with nonzero coefficient.

The next lemma shows that there are only few low-cone monomials in a non-zero $n$-variate polynomial.

---

*This manuscript is for review purposes only.*
Lemma 2.3 (Counting low-cones, [49, Lem 5]). The number of \( n \)-variate monomials with cone-size at most \( k \) is \( O(rk^2) \), where \( r := (3n/\log k)^{\log k} \).

The following lemma is the same as [49, Lemma 4]. It is proved by multivariate interpolation.

Lemma 2.4 (Coefficient extraction). Given a circuit \( C \), over the underlying field \( \mathbb{F}(\varepsilon) \), we can ‘extract’ the coefficient of a monomial \( m \) in \( C \); in \( \text{poly}(\text{size}(C), cs(m), d) \) time, where \( cs(m) \) denotes the cone-size of \( m \).

2.1. Basics of algebraic complexity. We will give a brief definition of various computational models and tools used in our results. Interested readers can refer [113, 47, 105] for more refined versions.

Algebraic Circuits, defined over a field \( \mathbb{F} \), are directed acyclic graphs with a unique root node. The leaf nodes of the graph is labelled by variables or field constants and internal nodes are either labelled with + or \( \times \). Further the edges can bear field constants. The output of the circuit, through root, is the polynomial it computes.

The size and depth of circuit is the size and depth of the underlying graph.

Circuit size. Some of the complexity parameters of a circuit are depth (number of layers), syntactic degree (the maximum degree polynomial computed by any node), fanin (maximum number of inputs to a node).

Operation on Complexity Classes. For class \( C \) and \( D \) defined over ring \( R \), our bloated model is any combination of sum, product, and division of polynomials from respective classes. For instance, \( C/D = \{ f/g : f \in C, 0 \neq g \in D \} \) similarly \( C \cdot D \) for products, \( C + D \) for sum, and other possible combinations. Also we use \( C_R \) to denote the basic ring \( R \) on which \( C \) is being computed over.

Hitting set. A set of points \( H \subseteq \mathbb{F}^n \) is called a hitting-set for a class \( C \) of \( n \)-variate polynomials if for any nonzero polynomial \( f \in C \), there exists a point in \( H \) where \( f \) evaluates to a nonzero value. A \( T(s) \)-time hitting-set would mean that the hitting-set can be generated in time \( \leq T(s) \), for input size \( s \).

Definition 2.5 (Algebraic Branching Program (ABP)). ABP is a computational model which is described using a layered graph with a source vertex \( s \) and a sink vertex \( t \). All edges connect vertices from layer \( i \) to \( i + 1 \). Further, edges are labelled by univariate polynomials. The polynomial computed by the ABP is defined as

\[ f = \sum_{\text{path } \gamma : s \rightarrow t} \text{wt}(\gamma) \]

where \( \text{wt}(\gamma) \) is product of labels over the edges in path \( \gamma \). Number of layers (\( \Delta \)) defines the depth and the maximum number of vertices in any layer (\( w \)) defines the width of an ABP. The size \( (s) \) of an ABP is the sum of the graph-size and the degree of the univariate polynomials that label. If \( d \) is the maximum degree of univariates then \( s \leq dw^2 \Delta \); in fact, we will take the latter as the ABP-size bound in our calculations.

We remark that ABP is closed under both addition and multiplication, which is straightforward from the definition. In fact, we also need to eliminate division in ABPs. Here is an important lemma stated below.

Lemma 2.6 (Strassen’s division elimination). Let \( g(x, y) \) and \( h(x, y) \) be computed by ABPs of size \( s \) and degree \( < d \). Further, assume \( h(x, 0) \neq 0 \). Then, \( g/h \mod y^d \) can be written as \( \sum_{i=0}^{d-1} C_i \cdot y^i \), where each \( C_i \) is of the form ABP/ABP of size \( O(sd^2) \).

Moreover, in case \( g/h \) is a polynomial, then it has an ABP of size \( O(sd^2) \).
DEMYSTIFYING THE BORDER OF DEPTH-3 ALGEBRAIC CIRCUITS

Proof. ABPs are closed under multiplication, which makes interpolation, wrt \( y \), possible. Interpolating the coefficient \( C_i \), of \( y^i \), gives a sum of \( d \) ABP/ABP’s; which can be rewritten as a single ABP/ABP of size \( O(sd^2) \).

Next, assume that \( g/h \) is a polynomial. For a random \((a, a_0) \in \mathbb{F}^{n+1}\), write \( h(x + a, y + a_0) = h(a, a_0) - \tilde{h}(x, y) \) and define \( g' := g(x + a, y + a_0) \). Clearly \( 0 \neq h(a, a_0) \in \mathbb{F} \) and \( \tilde{h} \) has a small ABP. Using the inverse identity in \( \mathbb{F}[x, y] \), we have \( g(x + a, y + a_0)/h(x + a, y + a_0) = \)

\[
\left(\frac{g'}{h(a, a_0)}\right)/(1 - \tilde{h}/h(a, a_0)) = (g'/h(a, a_0)) \cdot \left(\sum_{0 \leq i < d} (\tilde{h}/h(a, a_0))^i\right) \mod \langle x, y \rangle^d .
\]

Note that, the degree blowup in the above summands to \( O(d^2) \) and the ABP-size is \( O(sd) \). ABPs are closed under addition/multiplication; thus, we get an ABP of size \( O(sd^2) \) for the polynomial \( g(x + a, y + a_0)/h(x + a, y + a_0) \). This implies the ABP-size for \( g/h \) as well. \( \square \)

Our interest primarily is in the following two ABP-variants: ROABP and ARO.

**Definition 2.7** (Read-once Oblivious Algebraic Branching Program (ROABP)). An ABP is defined as Read-Once Oblivious Algebraic Branching Program (ROABP) in a variable order \((x_{\sigma(1)}, \ldots, x_{\sigma(n)})\) for some permutation \( \sigma : [n] \rightarrow [n] \), if edges of i-th layer of ABP are univariate polynomials in \( x_{\sigma(i)} \).

**Definition 2.8** (Any-order ROABP (ARO)). A polynomial \( f \in \mathbb{F}[x] \) is computable by ARO of size \( s \) if for all possible permutation of variables there exists a ROABP of size at most \( s \) in that variable order.

### 2.2. Properties of any-order ROABP (ARO).

We will start with defining the partial coefficient space of a polynomial \( f \) to ‘characterise’ the width of ARO. We can work over any field \( \mathbb{F} \).

Let \( A(x) \) be a polynomial over \( \mathbb{F} \) in \( n \) variables with individual degree \( d \). Denote the set \( M := \{0, \ldots, d\}^n \). Note that, one can write \( A(x) \) as

\[
A(x) = \sum_{\alpha \in M} \text{coef}_A(x^\alpha) \cdot x^\alpha.
\]

Consider a partition of the variables \( x \) into two parts \( y \) and \( z \), with \(|y| = k\). Then, \( A(x) \) can be viewed as a polynomial in variables \( y \), where the coefficients are polynomials in \( \mathbb{F}[z] \). For monomial \( y^\alpha \), let us denote the coefficient of \( y^\alpha \) in \( A(x) \) by \( A(y, a) \in \mathbb{F}[z] \). The coefficient \( A(y, a) \) can also be expressed as a partial derivative \( \partial A/\partial y^\alpha \), evaluated at \( y = 0 \) (and multiplied by an appropriate constant), see [51, Section 6]. Moreover, we can also write \( A(x) \) as

\[
A(x) = \sum_{a \in \{0, \ldots, d\}^k} A(y, a) \cdot y^\alpha.
\]

One can also capture the space by the coefficient matrix (also known as the partial derivative matrix) where the rows are indexed by monomials \( p_i \) from \( y \), columns are indexed by monomials \( q_j \) from \( z = x \setminus y \) and \((i, j)\)-th entry of the matrix is \( \text{coef}_{p_i, q_j}(f) \).

The following lemma formalises the connection between ARO width and dimension of the coefficient space (or the rank of the coefficient matrix).
Lemma 2.9 ([96]). Let $A(x)$ be a polynomial of individual degree $d$, computed by an ARO of width $w$. Let $k \leq n$ and $y$ be any prefix of length $k$ of $x$. Then
\[ \dim_f \{ A(y, a) \mid a \in \{0, \ldots, d\}^k \} \leq w. \]

We remark that the original statement was for a fixed variable order. Since, ARO affords any-order, the above holds for any-order as well. The following lemma is the converse of the above lemma and shows us that the dimension of the coefficient space is rightly captured by the width.

Lemma 2.10 (Converse lemma [96]). Let $A(x)$ be a polynomial of individual degree $d$ with $x = (x_1, \ldots, x_n)$, such that for some $w$, for any $1 \leq k \leq n$, and $y$, any-order-prefix of length $k$, we have
\[ \dim_f \{ A(y, a) \mid a \in \{0, \ldots, d\}^k \} \leq w. \]

Then, there exists an ARO of width $w$ for $A(x)$.

2.3. Properties of depth-3 diagonal circuits. In this section we will discuss various properties of $\Sigma \setminus \Sigma$ circuits and basic waring-rank. The corresponding bloated model is $\Sigma \setminus \Sigma / \Sigma \setminus \Sigma$, that computes elements of the form $f / g$, where $f, g \in \Sigma \setminus \Sigma$. The following lemma gives us a sum of powers representation of monomial. For proofs see [33, Proposition 4.3].

Lemma 2.11 (Waring identity for a monomial [33]). Let $M = x_1^{b_1} \cdots x_k^{b_k}$, where $1 \leq b_1 \leq \cdots \leq b_k$, and roots of unity $Z(i) := \{ z \in \mathbb{C} : z^{b_i+1} = 1 \}$. Then,
\[ M = \sum_{\varepsilon(i) \in Z(i), i = 2, \ldots, k} \gamma_{\varepsilon(2), \ldots, \varepsilon(k)} \cdot (x_1 + \varepsilon(2)x_2 + \ldots + \varepsilon(k)x_k)^d, \]
where $d := \deg(M) = b_1 + \cdots + b_k$, and $\gamma_{\varepsilon(2), \ldots, \varepsilon(k)}$ are scalars ($rk(M) := \prod_{i=2}^{k} (b_i+1)$ many.

Remark. For fields other than $\mathbb{F} = \mathbb{C}$: We can go to a small extension (at most $d^k$), for a monomial of degree $d$, to make sure that $\varepsilon(i)$ exists.

Using this, we show that $\Sigma \setminus \Sigma$ is closed under constant-fold multiplication.

Lemma 2.12 ($\Sigma \setminus \Sigma$ closed under multiplication). Let $f_i \in \mathbb{F}[x]$, of syntactic degree $\leq d_i$, be computed by a $\Sigma \setminus \Sigma$ circuit of size $s_i$, for $i \in [k]$. Then, $f_1 \cdots f_k$ has $\Sigma \setminus \Sigma$ circuit of size $O(\prod_{i=2}^{k} (d_i + 1) \cdot s_1 \cdots s_k)$.

Proof. Let $f_i := \sum_{i,j} f_{ij}^i$; by assumption $e_{ij} \leq d_i$. Each summand of $\prod_i f_i$ after expanding can be expressed as $\Sigma \setminus \Sigma$ using Theorem 2.11 of size at most $(d_2 + 1) \cdots (d_k + 1) \cdot \left( \sum_{i \in [k]} \text{size}(f_{ij}) \right)$. Summing up, for all $s_1 \cdots s_k$ many products, gives the upper bound.

Remark. The above lemma, and its proof, hold good for the more general $\Sigma \setminus \Sigma \setminus \Sigma$ circuits.

Using the additive and multiplicative closure of $\Sigma \setminus \Sigma$, we can show that $\Sigma \setminus \Sigma / \Sigma \setminus \Sigma$ is closed under constant-fold addition.

Lemma 2.13 ($\Sigma \setminus \Sigma / \Sigma \setminus \Sigma$ closed under addition). Let $f_i \in \mathbb{F}[x]$, of syntactic degree $d_i$, be computable by $\Sigma \setminus \Sigma / \Sigma \setminus \Sigma$ of size $s_i$, for $i \in [k]$. Then, $\sum_{i \in [k]} f_i$ has a $(\Sigma \setminus \Sigma / \Sigma \setminus \Sigma)$ representation of size $O((\prod_i d_i) \cdot \prod_i s_i)$. 

This manuscript is for review purposes only.
Proof. Let $f_i =: u_{i1} / u_{i2}$, where $u_{ij} \in \Sigma \land \Sigma$ of size at most $s_i$. Then

$$f = \sum_{i \in [k]} f_i = \left( \sum_{i \in [k]} u_{i1} \prod_{j \neq i} u_{j2} \right) / \left( \prod_{i \in [k]} u_{i2} \right).$$

Use Theorem 2.12 on each product-term in the numerator to obtain $\Sigma \land \Sigma$ of size $O((\prod_i d_i) \cdot \prod_i s_i)$. Trivially, $\Sigma \land \Sigma$ is closed under addition; so the size of the numerator is $O((\prod_i d_i) \cdot \prod_i s_i)$. Similar argument can be given for the denominator.

Remark. The above holds for $\Sigma \land \Sigma \land \Sigma \land \land$ circuits as well.

Using a simple interpolation, the coefficient of $y^e$ can be extracted from $f(x, y) \in \Sigma \land \Sigma$ again as a small $\Sigma \land \Sigma$ representation.

Lemma 2.14 ($\Sigma \land \Sigma$ coefficient extraction). Let $f(x, y) \in \mathbb{F}[x][y]$ be computed by a $\Sigma \land \Sigma$ circuit of size $s$ and degree $d$. Then, $\text{coef}_{y^e}(f) \in \mathbb{F}[x]$ is a $\Sigma \land \Sigma$ circuit of size $O(sd)$, over $\mathbb{F}[x]$.

Proof sketch. Let $f =: \sum_i \alpha_i \cdot \epsilon_i^e$, with $e \leq s$ and $\deg_y(f) \leq d$. Thus, write $f =: \sum_{i=0}^d f_i \cdot y^i$, where $f_i \in \mathbb{F}[x]$. Interpolate using $(d+1)$-many distinct points $y \mapsto \alpha_i$ in $\mathbb{F}$, and conclude that $f_i$ has a $\Sigma \land \Sigma$ circuit of size $O(sd)$.

Like coefficient extraction, differentiation of $\Sigma \land \Sigma$ circuit is easy too.

Lemma 2.15 ($\Sigma \land \Sigma$ differentiation). Let $f(x, y) \in \mathbb{F}[x][y]$ be computed by a $\Sigma \land \Sigma$ circuit of size $s$ and degree $d$. Then, $\partial_y(f)$ is a $\Sigma \land \Sigma$ circuit of size $O(sd^2)$, over $\mathbb{F}[x][y]$.

Proof sketch. Theorem 2.14 shows that each $f_e$ has $O(sd)$ size circuit where $f =: \sum_e f_e \cdot y^e$. Doing this for each $e \in [0, d]$ gives a blowup of $O(sd^2)$ and the representation: $\partial_y(f) = \sum_e f_e \cdot e \cdot y^{e-1}$.

Remark. Same property holds for $\Sigma \land \Sigma \land \land$ circuits.

Lastly, we show that $\Sigma \land \land$ circuit can be converted into ARO. In fact, we give the proof for a more general model $\Sigma \land \land \land$. The key ingredient for the lemma is the duality trick.

Lemma 2.16 (Duality trick [106]). The polynomial $f = (x_1 + \ldots + x_n)^d$ can be written as

$$f = \sum_{i \in [\ell]} f_{i1}(x_1) \cdots f_{in}(x_n),$$

where $t = O(nd)$, and $f_{ij}$ is a univariate polynomial of degree at most $d$.

We remark that the above proof works for fields of characteristic $= 0$, or $> d$.

Now, the basic idea is to convert $\land \land \land$ into $\Sigma \Pi \Sigma^{(1)} \land$ (i.e. sum-of-product-of-univarities) which is subsumed by ARO [65, Section 2.5.2].

Lemma 2.17 ($\Sigma \land \land \land$ as ARO). Let $f \in \mathbb{F}[x]$ be an $n$-variate polynomial com-putable by $\Sigma \land \land \land$ circuit of size $s$ and syntactic degree $D$. Then $f$ is computable by an ARO of size $O(sn^2D^2)$.

Proof sketch. Let $g^e = (g_1(x_1) + \cdots + g_n(x_n))^e$, where $\deg(g_i) \cdot e \leq D$. Using Theorem 2.16 we get $g^e = \sum_{i=1}^{O(ne)} h_{i1}(x_1) \cdots h_{in}(x_n)$, where each $h_{ij}$ is of degree at most $D$.

We do this for each power (i.e. each summand of $f$) individually, to get the final sum of product of univarities; of top-fanin $O(sne)$ and individual degree at most $D$.

This is an ARO of size $O(sne) \cdot n \cdot D \leq O(sn^2D^2)$.

This manuscript is for review purposes only.
2.4. Basic mathematical tools. For the time-complexity bound, we need to optimize the following function:

**Lemma 2.18.** Let $k \in \mathbb{N}_{\geq 2}$, and $h(x) := x(k-x)7^x$. Then, $\max_{i \in [k-1]} h(i) = h(k-1)$.

**Proof sketch.** Differentiate to get $h'(x) = (k-x)7^x - x7^x + x(k-x)(\log 7)7^x = 7^x \cdot \left( \frac{k}{2} - \frac{1}{\log 7} \right) + \sqrt{\left( \frac{k}{2} - \frac{1}{\log 7} \right)^2 - \frac{k}{\log 7}}$.

It vanishes at $x = \left(\frac{k}{2} - \frac{1}{\log 7}\right) + \sqrt{\left(\frac{k}{2} - \frac{1}{\log 7}\right)^2 - \frac{k}{\log 7}}$. Here is an important observation.

Here is an important lemma to show that positive valuation with respect to $y$,

**Lemma 2.19 (Valuation).** Let $f \in \mathbb{F}(x, y)$ such that $\text{val}_y(f) \geq 0$. Then, $f \in \mathbb{F}(x)[[y]] \cap \mathbb{F}(x, y)$.

**Proof sketch.** Let $f = g/h$ such that $g, h \in \mathbb{F}[x, y]$. Now, $\text{val}_y(f) \geq 0$, implies $\text{val}_y(g) \geq \text{val}_y(h)$. Let $\text{val}_y(g) = d_1$ and $\text{val}_y(h) = d_2$, where $d_1 \geq d_2 \geq 0$. Further, write $g = y^{d_1} \cdot \hat{g}$ and $h = y^{d_2} \cdot \hat{h}$. Write, $\hat{h} = h_0 + h_1 y + h_2 y^2 + \cdots + h_d y^d$, for some $d$; with $h_i \in \mathbb{F}[x]$. Note that $h_0 \neq 0$. Thus

$$f = y^{d_1-d_2} \cdot \frac{\hat{g}}{h_0} \cdot \frac{h_1}{h_0} \cdot \frac{h_2}{h_0} \cdot \cdots \cdot \frac{h_d}{h_0} \cdot y^0 \in \mathbb{F}(x)[[y]].$$

**Claim 2.20.** For our linear-map $\Psi$, and $g \in \Sigma^[[\delta]] : \Psi(g) \in \Sigma^[[\delta]]$ of size $3^\delta$.

**Proof sketch.** Each monomial $x^n$ of degree $\delta$, can produce $\prod_i (a_i + 1) \leq (\sum_i a_i + n) / n \leq (\delta / n + 1)^n$-many monomials, by AM-GM inequality as $\sum_i a_i \leq \delta$. As $\delta / n \to 0$, we have $(1 + \delta / n)^n \to e^\delta$. As $e < 3$, the upper bound follows.

2.5. De-bordering simple models. In this section we will discuss known de-bordering results of restricted models like product of sum of univariate and ARO.

Polynomials approximated by $\Pi \Sigma$ can be easily de-bordered [24, Prop.A.12]. In fact, it is the only constructive de-bordering result known so far. We extend it to show that same holds for polynomials approximated by $\Pi \Sigma \wedge$ circuits. In fact, we start it by showing a much more general theorem.

Let $C$ and $D$ be two classes over $\mathbb{F}[x]$. Consider the bloated-class $(C/C) \cdot (D/D)$, which has elements of the form $(g_1 / g_2) \cdot (h_1 / h_2)$, where $g_1 \in C$ and $h_1 \in D$ ($g_2 h_2 \neq 0$).

One can also similarly define its border (which will be an element in $\mathbb{F}(x)$). Here is an important observation.

**Lemma 2.21.** $(C/C) \cdot (D/D) \subseteq (C/C) \cdot (D/D)$.

**Proof.** Suppose $(g_1 / g_2) \cdot h_1 / h_2 = f + \varepsilon \cdot Q$, where $Q \in \mathbb{F}(x, \varepsilon)$ and $f \in \mathbb{F}(x)$. Let $\text{val}_c(g_i) := a_i$ and $\text{val}_c(h_i) := b_i$. Denote, $g_i := \varepsilon^{a_i} \cdot \hat{g}_i$, similarly $\hat{h}_i$. Further, assume $\hat{g}_i := \hat{g}_i + \varepsilon \cdot \hat{g}_i$; similarly for $\hat{h}_i$, we define $\hat{h}_i \in \mathbb{F}[x]$. Note that $\hat{g}_i \in \overline{C}$, similarly $\hat{h}_i \in \overline{D}$.

So, $\text{LHS} = \varepsilon^{a_1-a_2} b_1 + b_2 \cdot (\hat{g}_1 / \hat{g}_2) \cdot (\hat{h}_1 / \hat{h}_2)$. This has a limit $\lim_{\varepsilon \to 0}$, so $a_1 + b_1 - a_2 - b_2 \geq 0$. If it is $\geq 1$, the limit in RHS is 0 and so $f = 0$. If $a_1 + b_1 - a_2 - b_2 = 0$, then

$$f = (\hat{g}_1 / \hat{g}_2) \cdot (\hat{h}_1 / \hat{h}_2) \in (C/C) \cdot (D/D).$$

Now, we show an important de-bordering result on $\Pi \Sigma \wedge$ circuits.
Lemma 2.22 (De-bordering $\Pi \Sigma \Lambda$). Consider a polynomial $f \in \mathbb{F}[x]$ which is approximated by $\Pi \Sigma \Lambda$ of size $s$ over $\mathbb{F}(\varepsilon)[x]$. Then there exists a $\Pi \Sigma \Lambda$ (hence an ARO) of size $s$ which exactly computes $f(x)$.

Proof. We will show that $\Pi \Sigma \Lambda = \Pi \Sigma \Lambda \subseteq \text{ARO}$. From Theorem 2.1 (and its proof), it follows that $\Pi \Sigma \Lambda \subseteq \bigprod(\Sigma \Lambda)$. However, we note that $\Sigma \Lambda = \Sigma \Lambda$ and it does not change the size (as it can not increase the sparsity). Therefore, the size does not increase and further it is an ARO. Thus, the conclusion follows.

Next we show that polynomials approximated by ARO can be easily de-bordered. To the best of our knowledge the following lemma was sketched in [46]; also implicitly in [66].

Lemma 2.23 (De-bordering ARO). Consider a polynomial $f \in \mathbb{F}[x]$ which is approximated by ARO of size $s$ over $\mathbb{F}(\varepsilon)[x]$. Then, there exists an ARO of size $s$ which exactly computes $f(x)$.

Proof. By definition, there exists a polynomial $g = f + \varepsilon Q$ computable by width $w$ ARO over $\mathbb{F}(\varepsilon)[x]$. Note that $w \leq s$. In this proof, we will use the partial derivative matrix. With respect to any-order-prefix $y \subseteq x$, consider the partial derivative matrix $N(g)$. Using Theorem 2.9 and 2.10, we know $\text{rk}_{\mathbb{F}(\varepsilon)}(N(g)) \leq w$. This means determinant of any $(w+1) \times (w+1)$ minor of $N(g)$ is identically zero. One can see that the entries of the minor are coefficients of monomials of $g$ which are in $\mathbb{F}[\varepsilon][x \setminus y]$. Thus, determinant polynomial will remain zero even under the limit of $\varepsilon = 0$. Since, $\lim_{\varepsilon \to 0} g = f$, each minor (under limit) captures partial derivative matrix of $f$ of corresponding rows and columns. Thus, we get $\text{rk}_{\mathbb{F}}(N(f)) \leq w$. Theorem 2.10 shows that there exists an ARO, of width $w$ over $\mathbb{F}$, which exactly computes $f$.

An obvious consequence of Theorem 2.17 and Theorem 2.23 is the following de-bordering result.

Lemma 2.24 (De-bordering $\Sigma \Lambda \Sigma \Lambda$). Consider a polynomial $f \in \mathbb{F}[x]$ which is approximated by $\Sigma \Lambda \Sigma \Lambda$ of size $s$ over $\mathbb{F}(\varepsilon)[x]$ and syntactic degree $D$. Then there exists an ARO of size $O(s n^2 D^2)$ which exactly computes $f(x)$.

2.6. Basic PIT tools. We dedicate this section to discuss some basic PIT tools that we will require in the main section. We will start with the simplest one obtained using PIT lemma of [111, 120, 37, 99].

Lemma 2.25 (Trivial hitting set). For a class of $n$-variate, individual degree $< d$ polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$ there exists an explicit hitting-set $H \subseteq \mathbb{F}^n$ of size $d^n + 1$.

In other words, there exists a point $\bar{x} \in H$ such that $f(\bar{x}) \neq 0$ (if $f \neq 0$).

The above result becomes interesting when $n = O(1)$ as it yields a polynomial-time explicit hitting set. For general $n$, we have better results for restricted circuits, for eg. sparse circuits $\Sigma \Pi$, [2, 76] gave a map which reduces multivariate sparse polynomial into univariate polynomial of small degree, while preserving the non-identity. Since testing (low-degree) univariate polynomial is trivial, we get a simple PIT algorithm for sparse polynomials.

Indeed if identity of sparse polynomial can be tested efficiently, product of sparse polynomials $\Pi \Sigma \Pi$ can be tested efficiently. We formalise this in the following lemma.

Lemma 2.26 ([104, Lemma 2.3]). For the class of $n$-variate, degree $d$ polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$ computable by $\Pi \Sigma \Pi$ of size $s$, there exist an explicit hitting set of size $\text{poly}(s, d)$.

Finally, we state the best known PIT result for ARO, see [67, 60] for more details.
Theorem 2.27 (ARO hitting set). For the class of d-degree n-variate polynomials \( f \in \mathbb{F}[x] \) computable by size \( s \) ARO, there exists an explicit hitting set of size \( s^{O(\log \log s)} \).

The following lemma is useful to construct hitting set for product of two circuit classes when the hitting set of individual circuit is known.

Lemma 2.28. Let \( \mathcal{H}_1, \mathcal{H}_2 \subseteq \mathbb{F}^n \) of size \( s_1 \) and \( s_2 \) respectively be the hitting set of the class of n-variate degree d polynomials computable by \( C_1 \) and \( C_2 \) respectively. Then, for the class of polynomials computable by \( C_1 \cdot C_2 \) there is an explicit hitting set \( \mathcal{H} \) of size \( s_1 \cdot s_2 \cdot O(d) \).

Proof. Let \( f = f_1 \cdot f_2 \in C_1 \cdot C_2 \) such that \( f_1 \in C_1 \) and \( f_2 \in C_2 \). For each \( a \in \mathcal{H}_1 \), \( b \in \mathcal{H}_2 \) define a 'formal-sum' evaluation point (over \( \mathbb{F}[t] \)) \( c := (e_t)_{1 \leq t \leq n} \) such that \( c_x := a_t + b_t \); where \( t \) is a formal variable. Collect these points, going over \( i, j \), in a set \( H \). It can be seen, by shifting and scaling, that non-zeroness is preserved: there exists \( c \in H \) such that \( 0 \neq f(c) \in \mathbb{F}[t] \) and \( \deg f(c) = O(d) \). Using trivial hitting set from Theorem 2.25 we obtain the final hitting set \( \mathcal{H} \) of size \( O(s_1 \cdot s_2 \cdot d) \).

Remark. The above argument easily extends to circuit classes \((C_1/C_1) \cdot (C_2/C_2)\), which compute rationals of the form \((g_1/g_2) \cdot (h_1/h_2)\), where \( g_i \in C_1 \) and \( h_i \in C_2 \) \((g_2h_2 \neq 0)\).

3. De-bordering depth-3 circuits. In this section we will discuss the proof of de-bordering result (Theorem 1.1). Before moving on, we discuss the bloated model on which we will induct.

Definition 3.1 (Bloated model). We call a circuit \( C \in \text{Gen}(k, s) \), over the fractional ring \( R(x) \), with parameter \( k \) and size \( s \), if it computes \( f \in R(x) \) where \( f = \sum_{i \in [k]} T_i \), such that \( T_i = (U_i/V_i) \cdot P_i/Q_i \), with \( U_i, V_i, P_i, Q_i \in R[x] \) such that \( U_i, V_i \in \Pi^\Sigma \) and \( P_i, Q_i \in \Sigma^\Lambda^\Sigma \).

Further, size\((C) = \sum_{i \in [k]} \text{size}(T_i)\), and size\((T_i) = \text{size}(U_i) + \text{size}(V_i) + \text{size}(P_i) + \text{size}(Q_i)\).

It is easy to see that size-\( s \) \( \Sigma^{[k]} \Pi^{\Sigma} \) lies in \( \text{Gen}(k, s) \), which will be our general model of induction. Here is the main de-bordering theorem for depth-3 circuits.

Theorem 3.2 (De-bordering \( \Sigma^{[k]} \Pi^{\Sigma} \)). Let \( f(x) \in \mathbb{F}[x_1, \ldots, x_n] \), such that \( f \) can be computed by a \( \Sigma^{[k]} \Pi^{\Sigma} \)-circuit of size \( s \). Then \( f \) is also computable by an ABP (over \( \mathbb{F} \)), of size \( s^{O(\log^2 k)} \).

Proof. We will use DiDIL technique as discussed in subsection 1.4. The \( k = 1 \) case is obvious, as \( \Pi^{\Sigma} = \Sigma^\Lambda \) and trivially it has a small ABP. Further, as discussed before, \( k = 2 \) is already non-trivial. Eventually it involves de-bordering \( \text{Gen}(1, s) \); as DiDIL technique reduces the \( k = 2 \) problem to \( \text{Gen}(1, s) \) and then we interpolate.

Base step: De-bordering \( \text{Gen}(1, s) \). Let \( g(x, \varepsilon) \in R(x, \varepsilon) \) be approximating \( f \in R(x) \); here \( R \) is a commutative ring (the ring will be clear later in the next few paragraphs). We also assume the syntactic degree bound, of the denominator and numerator computing \( g \) to be \( d \). Here is the de-bordering result.

Claim 3.3. \( \text{Gen}(1, s) \in \text{ABP/ABP}, \) of size \( O(sd^4 n) \), while the syntactic degree blows up to \( O(nd^2) \).

Proof. Using Definition 3.1,

\[
g(x, \varepsilon) = (U(x, \varepsilon)/V(x, \varepsilon)) \cdot P(x, \varepsilon)/Q(x, \varepsilon) = f(x) + \varepsilon \cdot S(x, \varepsilon),
\]
where $U, V, P, Q \in \mathbb{R}(\varepsilon)[x]$ such that $U, V \in \Pi\Sigma, P, Q \in \Sigma\land\Sigma$. Let $a_1 := \text{val}_c(U), a_2 := \text{val}_c(V), b_1 := \text{val}_c(P)$ and $b_2 := \text{val}_c(Q)$. Extracting the maximum $\varepsilon$-power, we get

$$f + \varepsilon \cdot S = \varepsilon^{(a_1 - a_2) + (b_1 - b_2)} \cdot \left(\frac{U}{V}\right) \cdot \left(\frac{P}{Q}\right),$$

where $\tilde{U}, \tilde{V}, \tilde{P}, \tilde{Q} \in \mathbb{R}(\varepsilon)[x]$, and their valuations wrt. $\varepsilon$ are zero i.e. $\lim_{\varepsilon \to 0} \tilde{U}$ exists (similarly for $\tilde{V}, \tilde{P}, \tilde{Q}$). Since, LHS is well-defined at $\varepsilon = 0$, it must happen that $(a_1 - a_2) + (b_1 - b_2) \geq 0$. If $(a_1 - a_2) + (b_1 - b_2) \geq 1$, then $f = 0$, and we have trivially de-bordered. Therefore, we can assume $(a_1 - a_2) + (b_1 - b_2) = 0$ which implies that

$$f = \left(\lim_{\varepsilon \to 0} \frac{U}{V}\right) \cdot \left(\lim_{\varepsilon \to 0} \frac{P}{Q}\right) \in (\Pi\Sigma/\Pi\Sigma) \cdot (\text{ARO}/\text{ARO}) \subseteq \text{ABP/ABP}.$$

We have used the fact that $\tilde{U}, \tilde{V} \in \Pi\Sigma$ and $\tilde{P}, \tilde{Q} \in \Sigma\land\Sigma$ of size at most $s$, over $\mathbb{R}(\varepsilon)[x]$. Further, by Lemma 2.22 and Lemma 2.24, we know that $\Pi\Sigma = \Pi\Sigma$ and $\Sigma\land\Sigma \subseteq \text{ARO}$; therefore $f$ is computable by a ratio of two ABPs of size at most $O(s \cdot d^2 n)$ and the degree gets blown up to atmost $O(n d^2)$. \hfill \Box

**Bloat out: Reducing $\Sigma^k\Pi\Sigma$ to de-bordering $\text{Gen}(k-1, \cdot)$.** Let $f_0 := f$ be

an arbitrary polynomial in $\Sigma^k\Pi\Sigma$, approximated by $g_0 \in \mathbb{F}(\varepsilon)[x]$, computed by a depth-3 circuit $C$ of size $s$ over $\mathbb{F}(\varepsilon)$, i.e. $g_0 := f_0 + \varepsilon \cdot S_0$. Further, assume that $\deg(f_0) < a_0 := d \leq s$; we keep the parameter $d$ separately, to optimize the complexity later. Here, we also stress that one could think of homogeneous circuits and thus the degree can be assumed to be the syntactic degree as well. Then, $g_0 =: \sum_{i \in [k]} T_{i, 0}$, such that $T_{i, 0}$ is computable by a $\Pi\Sigma$-circuit of size at most $s$ over $\mathbb{F}(\varepsilon)$. Moreover, define $U_{i, 0} := T_{i, 0}$ and $V_{i, 0} := Q_{i, 0} = 1$ as the base input case (of $\text{Gen}(1, \cdot)$). As explained in the preliminaries, we do a safe division and derivation for reduction.

**$\Phi$ homomorphism.** To ensure invertibility and facilitate derivation, we define a homomorphism

$$\Phi : \mathbb{F}(\varepsilon)[x] \to \mathbb{F}(\varepsilon)[x, z], \text{ such that } x_i \mapsto z \cdot x_i + \alpha_i,$$

where $\alpha_i$ are random elements in $\mathbb{F}$. Essentially, it suffices to ensure that $\Phi(T_{i, 0})|_{x = \alpha} = T_{i, 0}(\alpha) \neq 0$ for all $i \in [k]$. We will be working with different ring $R_i(x)$, at $i$-th step of induction, with $R_0 := \mathbb{F}[z]/(z^d)$; here think of the $z$-variable as ‘cost-free’. The map $\Phi$ can be thought of as a ‘shift & scale’ map. In a way, choosing random $z$ and then shifting and scaling it back gives the original $f$. So, our target is to prove the size upper bound for $\Phi(f_0)$ over $R(x)$, and thereby prove upper bound for $f_0$.

**Divide and derive.** Let $v_{i, 0} := \text{val}_c(\Phi(T_{i, 0}))$. By $\Phi$-map, $v_{i, 0} \geq 0$, for each $i \in [k]$.

Further, wrt $\varepsilon$-valuation, assume that $\Phi(T_{i, 0}) := \varepsilon^{a_{i, 0}} \cdot \tilde{T}_{i, 0}$, where $\tilde{T}_{i, 0} := t_{i, 0} + \varepsilon \cdot \hat{t}_{i, 0}(x, z, \varepsilon)$. Note that, $v_{i, 0} = \text{val}_c(\tilde{T}_{i, 0})$. Without loss of generality, assume $\min_{i \in [k]} \text{val}_c(\tilde{T}_{i, 0}) = v_{k, 0}$, i.e. wrt $k$, otherwise we can rearrange. Then, we divide $\Phi(g_0)$ by $\tilde{T}_{k, 0}$ and derive wrt $z$.
show the general inductive reduction, we will illustrate these steps. That these two steps are needed in the general reduction as well, and thus once we looking and computing will be important later.

\[ \Phi(f_0)/\tilde{T}_{k,0} + \varepsilon \cdot \Phi(S_0)/\tilde{T}_{k,0} = \varepsilon^{x_{k,0}} + \sum_{i=1}^{k-1} \Phi(T_{i,0})/\tilde{T}_{k,0} \quad \text{[Divide]} \]

\[ \implies \partial_{\varepsilon} \left( \Phi(f_0)/\tilde{T}_{k,0} \right) + \varepsilon \partial_{\varepsilon} \left( \Phi(S_0)/\tilde{T}_{k,0} \right) = \sum_{i=1}^{k-1} \partial_{\varepsilon} \left( \Phi(T_{i,0})/\tilde{T}_{k,0} \right) \quad \text{[Derive]} \]

\[ (3.1) \]

\[ = \sum_{i=1}^{k-1} \left( \Phi(T_{i,0})/\tilde{T}_{k,0} \right) \cdot \log \left( \Phi(T_{i,0})/\tilde{T}_{k,0} \right) = : g_1. \]

\[ \text{Definability. Let } \mathcal{R}_1 := \mathbb{F}[z]/(z^{d_1}), \text{ and } d_1 := d_0 - v_{k,0} - 1. \text{ For } i \in [k - 1], \text{ define} \]

\[ T_{i,1} := (\Phi(T_{i,0})/\tilde{T}_{k,0}) \cdot \log(\Phi(T_{i,0})/\tilde{T}_{k,0}), \text{ and } f_1 := \partial_{\varepsilon} (\Phi(f_0)/t_{k,0}). \]

\[ \text{Claim 3.4. } g_1 \text{ approximates } f_1 \text{ correctly, i.e. } \lim_{\varepsilon \to 0} g_1 = f_1, \text{ where } g_1 \text{ (respectively } f_1) \text{ are well-defined over } \mathcal{R}_1(\varepsilon, x) \text{ (respectively } \mathcal{R}_1(x)). \]

\[ \text{Proof. As we divide by the minimum valuation, by Lemma 2.19 we have} \]

\[ \text{val}_z (\Phi(T_{i,0})/\tilde{T}_{k,0}) \geq 0 \implies \Phi(T_{i,0})/\tilde{T}_{k,0} \in \mathbb{F}(x, \varepsilon)[[z]] \implies T_{i,1} \in \mathbb{F}(x, \varepsilon)[[z]]. \]

\[ \text{Note that } \text{val}_z (\Phi(f_0) + \varepsilon \cdot S_0) = \text{val}_z (\sum_{i \in [k]} \Phi(T_{i,0})) \geq v_{k,0}. \text{ Setting, } \varepsilon = 0, \text{ implies that } \Phi(f_0)/\tilde{T}_{k,0} \in \mathbb{F}(x, \varepsilon)[[z]] \text{ (by Lemma 2.19).} \]

\[ \text{Moreover, } (\Phi(f_0)/\tilde{T}_{k,0})|_{\varepsilon = 0} = \Phi(f_0)/t_{k,0} \in \mathbb{F}(x, z). \text{ Combining these it follows that} \]

\[ \Phi(f_0)/t_{k,0} \in \mathbb{F}(x)[[z]] \implies f_1 \in \mathbb{F}(x)[[z]]. \]

\[ \text{Once we know that each } T_{i,1} \text{ and } f_1 \text{ are well-defined power-series, we claim that} \]

\[ \text{Eqn. (3.1) holds mod } z^{d_0 - v_{k,0} - 1}. \text{ Note that, } \Phi(f_0) + \varepsilon \cdot \Phi(S_0) = \sum_{i \in [k]} T_{i,1}, \text{ holds mod } z^d. \text{ Thus after dividing by the minimum valuation element (with } z\text{-valuation } v_{k,0}, \text{ it holds mod } z^{d_0 - v_{k,0}}; \text{ finally after differentiation it must hold mod } z^{d_0 - v_{k,0} - 1}. \]

\[ \text{Further, as } \lim_{\varepsilon \to 0} \tilde{T}_{k,0} \text{ exists, we must have } \partial_{\varepsilon} (\Phi(f_0)/t_{k,0}) = \lim_{\varepsilon \to 0} g_1; \text{ i.e. } g_1 \text{ approximates } f_1 \text{ correctly, over } \mathcal{R}_1(x). \]

\[ \text{However, we stress that we also think of these as elements over } \mathbb{F}(x, z, \varepsilon), \text{ with } z\text{-degree being ‘kept track of’ (which could be } > d). \text{ All these different ‘lenses’ of looking and computing will be important later.} \]

\[ \text{Now what with the lower fanin? The main claim now is to show that } 1) \ f_1 \in} \]

\[ \text{Gen}(k - 1, \cdot), \text{ and } 2) \text{ assuming we know Gen}(k - 1, \cdot) \text{ has small ABP/ABP, how to lift it for } f_0 \text{ (we will show how to generally reduce fanin in the next few paragraphs).} \]

\[ \text{To show that, we will show that each } T_{j,1} \text{ has small } (\Pi \Sigma/\Pi \Sigma) \cdot (\Sigma^{\Sigma}(\Sigma \Sigma)\Sigma)-\text{circuit over } \mathcal{R}_1(x, \varepsilon) \text{ and then we will interpolate. Once the degree of } z \text{ is maintained to be small, this interpolation would not be costly, which will finally achieve our goal; as polynomially many sum of ratios of ABPs is still a ratio of small ABPs. We remark that these two steps are needed in the general reduction as well, and thus once we show the general inductive reduction, we will illustrate these steps.} \]

\[ \text{Inductive step } (j\text{-th step): Reducing Gen}(k - j, \cdot) \text{ to } \text{Gen}(k - j - 1, \cdot). \text{ Suppose, we are at the } j\text{-th } (j \geq 1) \text{ step. Our induction hypothesis assumes} \]

\[ 1) \sum_{i \in [k - j]} T_{i,j} := g_j, \text{ over } \mathcal{R}_j(x, \varepsilon), \text{ such that it approximates } f_j \text{ correctly, where } f_j \in \mathcal{R}_j(x), \text{ where } \mathcal{R}_j := \mathbb{F}[z]/(z^{d_j}). \]
2. Here, \( T_{i,j} := (U_{i,j}/V_{i,j}) \cdot (P_{i,j}/Q_{i,j}) \), where

\[
U_{i,j}, V_{i,j} \in \Pi \Sigma \text{ and } P_{i,j}, Q_{i,j} \in \Sigma^\wedge \Sigma, \text{ each in } \mathcal{R}_j(\varepsilon)[x].
\]

Each can be thought as an element in \( \mathbb{F}(x, z, \varepsilon) \bigcap \mathbb{F}(x, \varepsilon)[[z]] \) as well. Assume that the syntactic degree of each denominator and numerator of \( T_{i,j} \) is bounded by \( D_j \).

3. \( v_{i,j} := \mathrm{val}_z(T_{i,j}) \geq 0 \), for \( i \in [k-j] \). Wlog, assume that \( \min_i v_{i,j} = v_{k-j,j} \).

Moreover, \( U_{i,j}|_{z=0} \in \mathbb{F}(\varepsilon) \setminus \{0\} \) (similarly for \( V_{i,j} \)).

We do like the \( j = 0 \)-th step done above, without applying any new homomorphism.

Similar to that reduction, we divide and derive to reduce the fanin further by 1.

**Divide and Derive.** Let \( T_{k-j,j} := \varepsilon^{a_{k-j,j}} \cdot \hat{T}_{k-j,j} \), where \( \hat{T}_{k-j,j} := (t_{k-j,j} + \varepsilon \cdot \bar{t}_{k-j,j}) \)

is not divisible by \( \varepsilon \). Divide \( g_j := f_j + \varepsilon \cdot S_j \), by \( \hat{T}_{k-j,j} \), to get:

\[
f_j/\hat{T}_{k-j,j} + \varepsilon \cdot S_j/\hat{T}_{k-j,j} = \varepsilon^{a_{k-j,j}} + \sum_{i=1}^{k-j-1} T_{i,j}/\hat{T}_{k-j,j}
\]

\[
\Rightarrow \partial_z \left( f_j/\hat{T}_{k-j,j} \right) + \varepsilon \cdot \partial_z \left( S_j/\hat{T}_{k-j,j} \right) = \sum_{i=1}^{k-j-1} \partial_z \left( T_{i,j}/\hat{T}_{k-j,j} \right)
\]

\[
(3.2) \quad = \sum_{i=1}^{k-j-1} \left( T_{i,j}/\hat{T}_{k-j,j} \right) \cdot \text{dlog} \left( T_{i,j}/\hat{T}_{k-j,j} \right)
\]

\[
=: g_{j+1}.
\]

**Definability.** Let \( \mathcal{R}_{j+1} := \mathbb{F}[z]/\langle z^{d_{j+1}} \rangle \), where \( d_{j+1} := d_j - v_{k-j,j} - 1 \). For \( i \in [k-j-1] \), define

\[
T_{i,j+1} := \left( T_{i,j}/\hat{T}_{k-j,j} \right) \cdot \text{dlog} \left( T_{i,j}/\hat{T}_{k-j,j} \right), \text{ and } f_{j+1} := \partial_z(f_j/t_{k-j,j}).
\]

**Claim 3.5 (Induction hypotheses).** (i) \( g_{j+1} \) (respectively \( f_{j+1} \)) are well-defined over \( \mathcal{R}_{j+1}(x, \varepsilon) \) (respectively \( \mathcal{R}_{j+1}(x) \)).

(ii) \( g_{j+1} \) approximates \( f_{j+1} \) correctly, i.e., \( \lim_{\varepsilon \to 0} g_{j+1} = f_{j+1} \).

**Proof.** Remember, \( f_j \) and \( T_{i,j} \)'s are elements in \( \mathbb{F}(x, z, \varepsilon) \) which also belong to \( \mathbb{F}(x, \varepsilon)[[z]] \). After dividing by the minimum valuation, by similar argument as in Claim 3.4, it follows that \( T_{i,j+1} \) and \( f_{j+1} \) are elements in \( \mathbb{F}(x, z, \varepsilon) \bigcap \mathbb{F}(x, \varepsilon)[[z]] \), proving the second part of induction-hypothesis-(2). In fact, trivially \( u_{i,j+1} \geq 0 \), for \( j \in [k-j-1] \) proving induction-hypothesis-(3).

Similarly, Eqn. (3.2) holds over \( \mathcal{R}_{j+1}(x, \varepsilon) \), or equivalently mod \( z^{d_{j+1}} \); this is because of the division by \( z \)-valuation of \( v_{k-j,j} \) and then differentiation, showing induction-hypothesis-(1). So, Eqn. (3.2) being computed mod \( z^{d_{j+1}} \) is indeed valid.

We also mention that using similar argument as in Claim 3.4, \( f_{j+1} \in \mathbb{F}(x)[[z]] \).

Finally, as \( f_{j+1} \) exists, it is obvious to see that \( \lim_{\varepsilon \to 0} g_{j+1} = f_{j+1} \). \( \square \)

**Invertibility of \( \Pi \Sigma \)-circuits.** Before going into the size analysis, we want to remark that the dlog computation plays a crucial role here and the invertibility of the \( \Pi \Sigma \)-circuits are crucial for our arguments to go through. The action \( \text{dlog}(\Sigma^\wedge \Sigma) \in \Sigma^\wedge \Sigma / \Sigma^\wedge \Sigma \), is of poly-size (Lemma 2.15).
What is the action on $\Pi \Sigma$? As $d\log$ distributes the product additively, so it suffices to work with $d\log(\Pi \Sigma)$; and we show that $d\log(\Pi \Sigma) \in \Sigma \land \Sigma$, is of poly-size. For the time being, assume these hold. Then, we simplify

$$T_{i,j} / T_{k-j,j} = \varepsilon^{-a_{k-j,i}} \cdot (U_{i,j} \cdot V_{k-j,j}) / (V_{i,j} \cdot U_{k-j,j} \cdot (P_{i,j} \cdot Q_{k-j,j}) / (Q_{i,j} \cdot P_{k-j,j}),$$

and its $d\log$. Therefore, one can define $U_{i,j+1} := \varepsilon^{-a_{k-j,i}} \cdot U_{i,j} \cdot V_{k-j,j}$; similarly $V_{i,j+1} := V_{i,j} \cdot U_{k-j,j}$. We stress that $d\log$ computation will produce $\Sigma \land \Sigma / \Sigma \land \Sigma$ which will further multiply with $P$'s and $Q$'s; it will be clear after the lemma. This directly means: $U_{i,j+1} |_{z=0}, V_{i,j+1} |_{z=0} \in F(\varepsilon) \setminus \{0\}$. This proves the second part of induction-hypothesis-(3).

The overall size blowup. Finally, we show the main step: how to use $d\log$ which is the crux of our reduction. We assume that at the $j$-th step, $\text{size}(T_{i,j}) \leq s_j$ and by assumption $s_0 \leq s$.

Claim 3.6 (Size blowup from DiDiL). $T_{1,k-1} \in (\Pi \Sigma / \Pi \Sigma) (\Sigma \land \Sigma / \Sigma \land \Sigma)$ over $\mathcal{R}_{k-1}(\sigma, \varepsilon)$ of size $s^{O(k^2)}$. It is computed as an element in $F(\varepsilon, x, z)$, with syntactic degree (in $x, z$) $d^{O(k)}$.

Proof. Steps $j = 0$ vs $j > 0$ are slightly different because of the homomorphism $\Phi$. However the main idea of using $d\log$ and expand it as a power-series is the same, which eventually shows that $d\log(\Pi \Sigma) \in \Sigma \land \Sigma$ with a controlled blowup.

For $j = 0$, we want to study $d\log$'s effect on $\Phi(T_{i,0}) / \tilde{T}_{k,0}$. As $d\log$ distributes over product and thus it suffices to study $d\log(\ell)$, where $\ell \in \mathcal{R}(\varepsilon)[x]$. However, by the property of $\Phi$, each $\ell$ must be of the form $\ell = A - z \cdot B$, where $A \in F(\varepsilon) \setminus \{0\}$ and $B \in F(\varepsilon)[x]$. Using the power series expansion, we have the following, over $\mathcal{R}_1(x, \varepsilon)$:

$$d\log(\ell) = -\frac{\partial_z (A - z \cdot B)}{A (1 - z \cdot B/A)} = -\frac{B}{A} \cdot \sum_{j=0}^{d_1-1} \left( \frac{z \cdot B}{A} \right)^j.$$  

(3.3)

Note, $(B/A)$ and $(-z \cdot B/A)^j$ have a trivial $\land \Sigma$ circuits, each of size $O(s)$. For all $j$ use Lemma 2.12 on $(B/A) \cdot (-z \cdot B/A)^j$ to obtain an equivalent $\Sigma \land \Sigma$ of size $O(j \cdot d \cdot s)$. Re-indexing gives us the final $\Sigma \land \Sigma$ circuit for $d\log(\ell)$ of size $O(d^3 \cdot s)$. We use the fact that $d_1 \leq d_0 = d$. Here the syntactic degree blowup to $O(d^2)$.

For $j > 0$, the above equation holds over $\mathcal{R}_j(x)$. However, as mentioned before, the degree could be $D_j$ (possibly $> d_j$) of the corresponding $A$ and $B$. Thus, the overall size after the power-series expansion would be $O(D_j^2 d s(\ell))$ [here again we use that $d_j \leq d$].

Effect of $d\log$ on $\Sigma \land \Sigma$ is, naturally, more straightforward because it is closed under differentiation, as shown in Lemma 2.15. Using Lemma 2.15, we obtain $\Sigma \land \Sigma / \Sigma \land \Sigma$ circuit for $d\log(\ell)$ of size $O(D_j^2 d_j s_j)$. Similar claim can be made for $d\log(Q_{i,j})$. Also, $d\log(U_{i,j} \cdot V_{k-j,j}) \in \sum d\log(\Sigma)$, which could be computed using the above Equation. Thus,

$$d\log(T_{i,j} / \tilde{T}_{k-j,j}) \in d\log(\Pi \Sigma / \Pi \Sigma) \pm [\Sigma [d] d\log(\Sigma \land \Sigma)$$

$$\subset \Sigma \land \Sigma + \Sigma [d] \Sigma \land \Sigma / \Sigma \land \Sigma = \Sigma \land \Sigma / \Sigma \land \Sigma .$$

Here, $\Sigma [d]$ means sum of 4-many expressions. The first containment is by linearization. Express $d\log(\Pi \Sigma / \Pi \Sigma)$ as a single $\Sigma \land \Sigma$-expression of size $O(D_j^2 d s_j)$, by summing up
DEMYSTIFYING THE BORDER OF DEPTH-3 ALGEBRAIC CIRCUITS

the $\Sigma\land\Sigma$-expressions obtained from $\text{dlog}(\Sigma)$. Next, there are 4-many $\Sigma\land\Sigma/\Sigma\land\Sigma$ expressions of size $O(D^2 s_j)$ as there are 4-many $P$'s and $Q$'s. Additionally, the syntactic degree of each denominator and numerator of $\Sigma\land\Sigma/\Sigma\land\Sigma$ grows up to $O(D_j)$. Finally, we club $\Sigma\land\Sigma/\Sigma\land\Sigma$ expressions (4 of them) to express it as a single $\Sigma\land\Sigma/\Sigma\land\Sigma$ expression using Lemma 2.15, with size blowup of $O(D_j^{12} s_j^2)$. Finally, add the single $\Sigma\land\Sigma$ expression of size $O(D_j^3 s_j)$, and degree $O(dD_j)$, to get $O(s_j^3 D_j^{16} d)$ size representation.

Also, we need to multiply with $T_{i,j} / \tilde{T}_{k-j,j}$ which is of the form $(\Pi \Sigma / \Pi \Sigma) \cdot (\Sigma\land\Sigma/\Sigma\land\Sigma)$, where each $\Sigma\land\Sigma$ is basically product of two $\Sigma\land\Sigma$ expressions of size $s_j$ and syntactic degree $D_j$ and clubbed together, owing a blowup of $O(D_j s_j^2)$. Hence, multiplying this $(\Pi \Sigma / \Pi \Sigma) \cdot (\Sigma\land\Sigma/\Sigma\land\Sigma)$-expression with the $\Sigma\land\Sigma/\Sigma\land\Sigma$ expression obtained from $\text{dlog}$-computation, gives a size blowup of $s_{j+1} := s_j^2 D_j^{O(1)} d$.

As mentioned before, the main blowup of syntactic degree in the $\text{dlog}$-computation could be $O(dD_j)$ and clearing expressions and multiplying the without-dlog expression increases the syntactic degree only by a constant multiple. Therefore, $D_{j+1} := O(dD_j) \implies D_j = d^{O(j)}$. Hence, $s_{j+1} = s_j^2 \cdot d^{O(j)} \implies s_j \leq (sd)^{O(j^7)}$. In particular, $s_{k-1} \leq s^{O(k^7)}$; here we used that $d \leq s$. This calculation quantitatively establishes induction-hypothesis (2). 

Roadmap to trace back $f_0$. The above claim established that $g_{k-1} \in \text{Gen}(1, \cdot)$ and approximates $f_{k-1}$ correctly. We also know that $\text{Gen}(1, \cdot) \in \text{ABP/ABP}$, from Claim 3.3.

Whence, $g_{k-1}$ having $s^{O(k^7)}$-size bloated-circuit implies: it can be computed as a ratio of ABPs with size $s^{O(k^7)} \cdot D_{k-1}^4 \cdot n = s^{O(k^7)}$, and syntactic degree $n \cdot D_{k-1}^2 = d^{O(k)}$. Now, we recursively ‘lift’ this quantity, via interpolation, to recover in order, $f_{k-2}, f_{k-3}, \ldots, f_0$; which we originally wanted.

Interpolation: To integrate and limit. As mentioned above, we will interpolate recursively. We know $f_{k-1} = \partial_z (f_{k-2}/t_{2,k-2})$ has a ABP/ABP circuit over $\mathbb{F}(x, z)$, i.e. each denominator and numerator is being computed in $\mathbb{F}[x, z]$, and size bounded by $S_{k-1} := s^{O(k^7)}$. Here is an important claim about the size of $f_{k-2}$ (we denote it by $S_{k-2}$).

Claim 3.7 (Tracing back one step). $f_{k-2}$ can be expressed as

$$f_{k-2} = \sum_{i=0}^{d_{k-2}-1} (\text{ABP/ABP}) z^i,$$

of size $s^{O(k^7)}$ and syntactic degree $d^{O(k)}$.

Proof. Let the degree of $f_{k-1}$ (both denominator and numerator) be bounded by $D_{k-1} := d^{O(k)}$ and further we know that keeping information (of the power series) till mod $z^{d_{k-1}}$ suffices. While computing it, it may happen that valuation of each denominator and numerator is $> 0$, i.e. it is of the form $z^{e_1} \cdot (\text{ABP})/z^{e_2} \cdot (\text{ABP})$ ($e_1, e_2$ being valuations wrt $z$). It must happen that $e_1 \geq e_2$, if it is indeed a power series in $z$; the $e_i$’s are bounded by $D_{k-1}$. Furthermore, these ABPs (after dividing by $z$-power) have similar size as $z$ is considered free [think of them being computed over $\mathbb{F}(z)[x]$]. Therefore, $\text{ABP/ABP}$ can be expressed as $\sum_{i=0}^{d_{k-1}-1} C_{i,k-1} \cdot z^i$, by using the inverse identity: $1/(1 - z) \equiv 1 + \ldots + z^{d_{k-1}-1} \mod z^{d_{k-1}}$. Here, each $C_{i,k-1}$ has an $\text{ABP/ABP}$ of size at most $O(S_{k-1} \cdot D_{k-2}^2)$; for details see Lemma 2.6.
Once we get \( f_{k-1} = \sum_{i=0}^{d_{k-1}-1} C_{i,k-1} z^i \), definite-integration implies:

\[
f_{k-2}/t_{2,k-2} - f_{k-2}/t_{2,k-2}|_{z=0} = \sum_{i=1}^{d_{k-1}} (C_{i,k-1}/i) \cdot z^i \mod z^{d_{k-1}+1}.
\]

The final trick is to get \( f_{k-2}/t_{2,k-2}|_{z=0} \) and ‘reach’ \( f_{k-2} \). As, \( f_{k-2}/t_{2,k-2} \in \mathbb{F}(\varepsilon)\), substituting \( z = 0 \) yields an element in \( \mathbb{F}(\varepsilon) \). Recall the identity:

\[
f_{k-2}/t_{2,k-2}|_{z=0} = \lim_{\varepsilon \to 0} (T_{1,k-2}/\hat{T}_{2,k-2}|_{z=0} + \varepsilon^{a_{2,k-2}})
\]

\[
\in \lim_{\varepsilon \to 0} (\mathbb{F}(\varepsilon) \cdot (\Sigma \land \Sigma/\Sigma \land \Sigma) + \varepsilon^{a_{2,k-2}}).
\]

Since, \( \mathbb{F}(\varepsilon) \cdot (\Sigma \land \Sigma/\Sigma \land \Sigma) + \varepsilon^{a_{2,k-2}} \in \Sigma \land \Sigma/\Sigma \land \Sigma \), over \( \mathbb{F}(\varepsilon) \). We know that the limit exists and is ARO/ARO (\( \subseteq \) ABP/ABP) of syntactic degree \( d^{O(k)} \) and size \( s_{k-1} \cdot d^{O(k)} \).

Thus, from the above equation, it follows:

\[
f_{k-2}/t_{2,k-2} = f_{k-2}/t_{2,k-2}|_{z=0} + \sum_{i=1}^{d_{k-1}} (C_{i,k-1}/i) \cdot z^i \in \sum_{i=0}^{d_{k-1}} (\text{ABP}/\text{ABP}) \cdot z^i,
\]

of size \( d_{k-1} \cdot S_{k-1} \cdot D_{k-1}^2 + s_{k-1} \cdot d^{O(k)} \), and degree \( D'_{k-1} + d^{O(k)} \). Lastly,

\[
t_{2,k-2} \in \lim_{\varepsilon \to 0} (\Pi \Sigma/\Pi \Sigma) \cdot (\Sigma \land \Sigma/\Sigma \land \Sigma) \subseteq (\Pi \Sigma/\Pi \Sigma) \cdot (\text{ARO}/\text{ARO}).
\]

Thus, it has size \( s_{k-2} \), by previous Claims and degree bound \( D_{k-2} \). Moreover, we know that \( \text{val}_x(t_{2,k-2}) \geq v_{2,k-2} = d_{k-2} - d_{k-1} - 1 \). Thus, multiply \( t_{2,k-2} \) and truncate it till \( d_{k-2} - 1 \). This gives us the blowup: size \( S_{k-2} = d_{k-1} \cdot S_{k-1} \cdot D_{k-1}^2 + s_{k-1} \cdot d^{O(k)} \) and degree \( D'_{k-2} = D'_{k-1} + d^{O(k)} \).

So, we get: \( f_{k-2} \) has \( \sum_{i=0}^{d_{k-2}-1} (\text{ABP}/\text{ABP}) z^i \) of size \( S_{k-2} = s^{O(k^2)} \) and degree \( D'_{k-2} = d^{O(k)} \).

The \( z=0 \) evaluation. To trace back further, we imitate the step as above; and get \( f_j \) one by one. But we first need a claim about the \( z=0 \) evaluation of \( f_j/t_{k-j,j} \).

**Claim 3.8 (For definite integration).** \( f_j/t_{k-j,j}|_{z=0} \in \text{ARO}/\text{ARO} \subseteq \text{ABP}/\text{ABP} \) of size \( s^{O(k^2)} \).

**Proof.** Note that, \( g_j/\hat{T}_{k-j,j} = \sum_{i \in [k-j]} T_{i,j}/\hat{T}_{k-j,j} \in \mathbb{F}(\varepsilon)[[z,\varepsilon]] \), as valuation wrt \( z \) respectively \( \varepsilon \) is non-negative. Therefore,

\[
\left( \frac{f_j}{t_{k-j,j}} \right)|_{z=0} = \lim_{\varepsilon \to 0} \sum_{i \in [k-j]} \left( \frac{T_{i,j}}{\hat{T}_{k-j,j}} \right)|_{z=0}
\]

\[
= \lim_{\varepsilon \to 0} \sum_{i \in [k-j]} \left( \varepsilon^{-a_{k-j,j}} \cdot \frac{U_{i,j} \cdot V_{k-j,j}}{U_{k-j,j} \cdot V_{i,j}} \cdot \frac{P_{i,j} \cdot Q_{k-j,j}}{P_{k-j,j} \cdot Q_{i,j}} \right)|_{z=0}
\]

\[
\in \lim_{\varepsilon \to 0} \sum_{i \in [k-j]} \left( \mathbb{F}(\varepsilon) \cdot \frac{\Sigma \land \Sigma}{\Sigma \land \Sigma} \right) = \lim_{\varepsilon \to 0} \frac{\Sigma \land \Sigma}{\Sigma \land \Sigma} \subseteq \text{ARO}/\text{ARO}.
\]

Here we crucially used induction-hypothesis-(3) part: each \( U_{i,j}, V_{i,j} \) at \( z = 0 \), is an element in \( \mathbb{F}(\varepsilon) \). Also, we used that \( \Sigma \land \Sigma \) is closed under constant-fold multiplication (Lemma 2.12). Finally, we take the limit to conclude that \( \Sigma \land \Sigma/\Sigma \land \Sigma \subseteq \text{ARO}/\text{ARO} \).
To show the ABP-size upper bound, let us denote the size($f_j/t_{k-j,j}|_{z=0}$) = $S_j'$, and the syntactic degree $D_j'$. We claim that $S_j' = O(s_j^{O(k-j)} \cdot D_j'^4 \cdot n)$. Because, we have a sum of $k-j$ many $\Sigma \land \Sigma$ expressions each of size $s_j$; $\Sigma \land \Sigma$ is closed under multiplication (Lemma 2.12) and $\Sigma \land \Sigma$ to ARO conversion introduces exponent 4 in the degree (Lemma 2.17). Each time the syntactic degree blowup is only a constant multiple, thus $D_j' := d^O(k)$ (which is $\leq s^{O(k)}$). Therefore, $S_j' = s^{O(k-j) \cdot 7^j} = s^{O(k \cdot 7^j)}$. Here, we use the fact that $\text{max}_{j \in [k]} j(k-j)7^j = (k-1)7^{k-1}$ (see Lemma 2.18). This finishes the proof.

**Size blowup.** Suppose the ABP-size of $f_j$ is $S_j$; thus we need to estimate $S_0$.

We remark that we do not need to eliminate division at each tracing-back-step (which we did to obtain $f_{k-2}$). Since once we have $\sum_{i=0}^{d_0-1} (\text{ABP}/\text{ABP}) \cdot z^i$, it is easy to integrate (wrt $z$) without any blowup as we already have all the ABP/ABP’s in hand (they are z-free). The main size blowup ($= S_j'$) happens due to $z = 0$ computation which we calculated above (Claim 3.8). Thus, the final recurrence is $S_j = S_{j+1} + S_j'$. This gives $S_0 = s^{O(k \cdot 7^k)}$, which is the size of $\Phi(f)$, over $F(z, x)$, being computed as an ABP/ABP.

Finally, plugging ‘random’ $z$, shifting-and-scaling, gives us $f$; represented as an ABP/ABP of similar size. At the final stage, we eliminate the division-gate which gives us $f$ represented as an ABP of size $s^{O(k \cdot 7^k)}$.

**Remark.** Our proof de-bordered Gen$(k, s)$, and that too for any field of characteristic $= 0$ or $\geq d$.

4. **Blackbox PIT for border depth-3 circuits.** We divide the section into two parts. First subsection deals with proving Theorem 1.2, while the second subsection deals with optimally better hitting sets in the log-variate regime.

4.1. **Quasi-derandomizing $\Sigma[k] \Pi[\Sigma]$ circuits.** Induction step of DiDiL is important to give any meaningful upper bound of circuit complexity. However, hitting set construction demands less—each inductive step of fanin reduction must preserve non-zeroness. Eventually, we exploit this to give an efficient hitting set construction for $\Sigma[k] \Pi[\Sigma]$, and in the process of reducing the top fanin analyse the bloated model Gen$(k, \cdot)$.

**Theorem 4.1** (Efficient hitting set for $\Sigma[k] \Pi[\Sigma]$). There exists an explicit quasi-polynomial time ($s^{O(k \cdot 7^k \cdot \log \log s)}$) hitting set for $\Sigma[k] \Pi[\Sigma]$-circuits of size $s$ and constant $k$.

**Proof.** The basic reduction strategy is same as section 3. Let $f_0 := f$ be an arbitrary polynomial in $\Sigma[k] \Pi[\Sigma]$, approximated by $g_0 \in F(\varepsilon)[x]$, computed by a depth-3 circuit $C$ of size $s$ over $F(\varepsilon)$, i.e. $g_0 := f_0 + \varepsilon \cdot S_0$. Further, assume that deg($f_0) < d_0 := d \leq s$. Let $g_0 := \sum_{i \in [k]} T_{i,0}$, such that $T_{i,0}$ is computable by a $\Pi[\Sigma]$-circuit of size atmost $s$ over $F(\varepsilon)$. As before, define $R_0 := F(z)/\langle z^d \rangle$. Thus, $f_0 + \varepsilon \cdot S_0 = \sum_{i \in [k]} T_{i,0}$, holds over $R_0(x, \varepsilon)$.

Define $U_{i,0} := T_{i,0}$ and $V_{i,0} := P_{i,0} := Q_{i,0} = 1$ to set the input instance of Gen$(k, s)$. Of course, we assume that each $T_{i,0} \neq 0$ (otherwise it is a smaller fanin than $k$).

Φ **homomorphism.** To ensure invertibility and facilitate derivation, we define the same Φ as in section 3, i.e. $\Phi : F(\varepsilon)[x] \to F(\varepsilon)[x, z]$ such that $x_i \mapsto z \cdot x_i + \alpha_i$. For the upper bound proof, we took $\alpha_i \in F$ to be random; but for the PIT purpose, we cannot...
work with a random shift. The purpose of shifting was to ensure the invertibility,
which is, $F(z) \ni T_{i,0}(\alpha) \neq 0$; that is easy to ensure since $f(y, y^2, \ldots, y^n) \neq 0$, for any linear
polynomial $f$, over any field. Since, $\deg(\prod T_{i,0}) \leq s$, $\alpha = (i, i^2, \ldots, i^n)$, for some
$i \in [s]$ works! In the proof, we will work with every such $\alpha$ ($s$-many), and for the
right-value, non-zeroness will be preserved, which suffices.

0-th step: Reduction from $k$ to $k - 1$. We will use the same notation as in section 3.
We know that $g_1$ approximates $f_1$ correctly over $R_1(x, \varepsilon)$. Rewriting the same, we have
\begin{equation}
(4.1)
\end{equation}
\[ f_0 + \varepsilon \cdot S_0 = \sum_{i \in [k]} T_{i,0}, \text{ over } R_0(x, \varepsilon) \implies f_1 + \varepsilon \cdot S_1 = \sum_{i \in [k-1]} T_{i,1}, \text{ over } R_1(x, \varepsilon). \]
Here, define $T_{i,1} := (\Phi(T_{i,0})/\tilde{T}_{k,0}) \cdot d\log(\Phi(T_{i,0})/\tilde{T}_{k,0})$, for $i \in [k - 1]$ and $f_1 :=$
\[ \partial_z (\Phi(f_0)/\tilde{T}_{k,0}), \text{ same as before. Also, we will consider } T_{i,1} \text{ as an element of } F(x, z, \varepsilon) \]
and keep track of $\deg(z)$.

The “iff” condition. Note that the equality in Equation 4.1 over $R_1(\varepsilon, x)$ is only
“one-sided”. Whereas, to reduce identity testing, we need a necessary and sufficient
condition: If $f_0 \neq 0$, we would like to claim that $f_1 \neq 0$ (over $R_1(x)$). However, it may
not be directly true because of the loss of $z$-free terms of $f_0$, due to differentiation.
Note that $f_1 \neq 0$ implies $\text{val}_z(f_1) < d := d_1$. Further, $f_1 = 0$, over $R_1(x)$, implies–
either, (1) $\Phi(f_0)/\tilde{T}_{k,0}$ is $z$-free. This implies $\Phi(f_0)/\tilde{T}_{k,0}$, for which $f_0$
implies it is in $F$, because $z$-free implies $x$-free, by substituting $z = 0$, by the definition
of $\Phi$. Also, note that $f_0, T_{k,0} \neq 0$ implies $\Phi(f_0)/\tilde{T}_{k,0}$ is a non-zero element in $F$. Thus,
it suffices to check whether $\Phi(f_0)|_{z=0} = f_0(\alpha)$ is non-zero or not.

or, (2) $\partial_z(\Phi(f_0)/\tilde{T}_{k,0}) = z^{d_1} \cdot p$ where $p \in F(z, x)$ s.t. $\text{val}_z(p) \geq 0$. By simple
power series expansion, one can conclude that $p \in F(x)[[z]]$ (Lemma 2.19). Hence, $\Phi(f_0)/\tilde{T}_{k,0} = z^{d+1} \cdot \tilde{p}$, where $\tilde{p} \in F(x)[[z]] \implies \text{val}_z(\Phi(f_0)) \geq d$,
a contradiction. Here we used the simple fact that differentiation decreases the valu-
ation by 1.

Conversely, it is obvious that $f_0 = 0$ implies $f_1 = 0$. Thus, we have proved the
following:
\[ f_0 \neq 0 \text{ over } F[x] \iff f_1 \neq 0 \text{ over } R_1(x), \text{ or } 0 \neq \Phi(f_0)|_{z=0} \in F. \]
Recall, Claim 3.6 shows that $T_{i,1} \in (\Pi\Sigma/\Pi\Sigma) (\Sigma^\land \Sigma/\Sigma^\land \Sigma)$ with a polynomial blowup.
Therefore, subject to $z = 0$ test, we have reduced the identity testing problem to $k - 1$.
We will recurse over this until we reach $k = 1$.

Induction step. Assume that we are at the end of $j$-th step ($j \geq 1$). Our inductive
hypothesis assumes the following invariants:
1. $\sum_{i \in [k-j]} T_{i,j} = f_j + \varepsilon \cdot S_j$ over $R_j(x, \varepsilon)$, where $T_{i,j} \neq 0$ and $R_j := F[z]/(z^{d_j})$.
2. $\text{val}_z(T_{i,j}) \geq 0$, for all $i \in [k - j]$ (similarly $V_{i,j}$).
4. $f_0 \neq 0$ iff: $f_j \neq 0$ over $R_j(x)$, or $\sqrt[n]{1/n} (f_{i-1}/T_{k-1, i})_{i=0} \neq 0$, over $F(x)$.
Reducing the problem to $k - j - 1$. We will follow the $j = 0$ case, without applying
any homomorphism. Again, this reduction step is exactly the same as before, which
yields: $f_j + \varepsilon \cdot S_j = \sum_{i \in [k-j]} T_{i,j}$, over $R_j(x, \varepsilon) \implies$
\begin{equation}
(4.2)
\end{equation}
\[ f_{j+1} + \varepsilon \cdot S_{j+1} = \sum_{i \in [k-j-1]} T_{i,j+1}, \text{ over } R_{j+1}(x, \varepsilon). \]
Here, $T_{i,j+1} := (T_{i,j}/\tilde{T}_{k-j,j}) \cdot \log(T_{i,j}/\tilde{T}_{k-j,j})$, and $f_{j+1} := \partial_z(f_j/t_{k-j,j})$, as before.

It remains to show that, all the invariants assumed are still satisfied for $j + 1$. The first 3 invariants are already shown in section 3. The 4-th invariant is the iff condition to be shown below.

The “iff” condition in the induction. The above Equation 4.2 pioneers to reduce from $k - j$-summands to $k - j - 1$. But we want an ‘iff’ condition to efficiently reduce the identity testing. If $f_{j+1} \neq 0$, then $\text{val}_z(f_{j+1}) < d_{j+1}$. Further, $f_{j+1} = 0$, over $R_{j+1}(x)$ implies–

either, (1) $f_j/t_{k-j,j} = z^{d_{j+1}} \cdot p$, where $p \in \mathbb{F}(z,x)$ s.t. $\text{val}_z(p) \geq 0$. By simple power series expansion, one concludes that $p \in \mathbb{F}(x)[[z]]$ (Lemma 2.19). Hence,

$$\frac{f_j}{t_{k-j,j}} \in z^{d_{j+1}} \cdot \tilde{p},$$

where $\tilde{p} \in \mathbb{F}(x)[[z]] \implies \text{val}_z(f_j) \geq d_j \implies f_j = 0$, over $R_{j}(x)$.

Conversely, $f_j = 0$, over $R_{j}(x)$, implies $\text{val}_z(f_j/T_{k-j,j}) \geq d_j - v_{k-j,j} \implies \text{val}_z(\partial_z(f_j/T_{k-j,j})) \geq d_j - v_{k-j,j} - 1 = d_{j+1} \implies \partial_z(f_j/T_{k-j,j}) = 0$, over $R_{j+1}(x)$.

Fixing $\varepsilon = 0$ we deduce $f_{j+1} = \partial_z(f_j/t_{k-j,j}) = 0$.

Thus, we have proved that $f_j \neq 0$ over $R_j(x)$ iff

$$f_{j+1} \neq 0 \text{ over } R_{j+1}(x), \text{ or } 0 \neq (f_j/t_{k-j,j})|_{z=0} \in \mathbb{F}(x).$$

This concludes the proof of the 4-th invariant.

Note: In the above substitution ($z = 0$), $\Sigma \times \Sigma / \Sigma \times \Sigma$ maybe undefined by directly evaluating at numerator and denominator, i.e. $= 0/0$. But we can keep track of the $z$ degree of numerator and denominator, which will be polynomially bounded as seen in Claim 3.6. We can interpolate and cancel the $z$-powers to get the ratio.

Constructing the hitting set. The above discussion has reduced the problem of testing $\Phi(f)$ to testing $f_{k-1}$ or $f_j/t_{k-j,j}|_{z=0}$, for $j \in [k-2]$. We know that $f_{k-1} \in \mathbf{P}(\mathbf{I} \Sigma / \mathbf{P} \Sigma) \cdot \text{ARO/ARO}$, of size $s^{O(k^7)}$, from Claim 3.6. We obtain the hitting set of $\Pi \Sigma$ from Theorem 2.26, and for $\Sigma \times \Sigma$ we obtain the hitting set from Theorem 2.27 (due to Lemma 2.17). Finally we combine the two hitting sets using Lemma 2.28 and use the fact that the syntactic degree is bounded by $s^{O(k)}$ to obtain a hitting set $\mathcal{H}_{k-1}$ of size $s^{O(k^7 \log \log s)}$.

However, it remains to show (1) efficient hitting set for $f_j/t_{k-j,j}|_{z=0}$, for $j \in [k-2]$, and most importantly (2) how to translate these hitting sets to that of $\Phi(f)$.

Recall: Claim 3.8 shows that $f_k/t_{k-j,j}|_{z=0} \in \text{ARO/ARO}$, of size $s^{O(k^7)}$ (over $\mathbb{F}(x)$). Thus, it has a hitting set $\mathcal{H}_j$ of size $s^{O(k^7 \log \log s)}$ (Theorem 2.27).

To translate the hitting set, we need a small property which will bridge the gap of lifting the hitting set to $f_0$.

CLAIM 4.2 (Fix x). For $b \in \mathbb{F}^n$, if the following two things hold: (i) $f_{j+1}|_{x=b} \neq 0$, over $R_{j+1}$, and (ii) $\text{val}_z(T_{k-j,j}|_{z=b}) = v_{k-j,j}$, then $f_j|_{x=b} \neq 0$, over $R_j$.

Proof. Suppose the hypothesis holds, and $f_j|_{x=b} = 0$, over $R_j$. Then,

$$\text{val}_z \left( \left( \frac{f_j}{T_{k-j,j}} \right) \bigg|_{x=b} \right) \geq d_j - v_{k-j,j} \implies \text{val}_z \left( \left( \frac{f_j}{T_{k-j,j}} \right) \bigg|_{x=b} \right) \geq d_{j+1}.$$
The last condition implies that \( \partial_{x_j} (f_j/\tilde{T}_{k-j,j}) |_{x=b} = 0 \), over \( R_{j+1}(x) \). Fixing \( \varepsilon = 0 \) we deduce \( f_{j+1}|_{x=b} = 0 \). This is a contradiction! 

Finally, we have already shown in section 3 that \( \tilde{T}_{k-j,j} \in (\Pi \Sigma / \Pi \Sigma) \cdot (\Sigma \Lambda / \Sigma \Lambda) \), and \( t_{k-j,j} \in (\Pi \Sigma / \Pi \Sigma) \cdot (\Sigma \Lambda / \Sigma \Lambda) \), of size \( s^{O(k^2)} \), which is similar to \( f_{k-1} \). Note: \( \text{val}_{\varepsilon} \) of a \( \Sigma \Lambda \Sigma \) again reduces to a \( \Sigma \Lambda \Sigma \) question.

Joining the dots: The final hitting set. We now have all the ingredients to construct the hitting set for \( \Phi(f_0) \). We know \( H_{k-1} \) works for \( f_{k-1} \) (as well as \( t_{2,k-2} \), because they both are of the same size and belong to \( (\Pi \Sigma / \Pi \Sigma) \cdot (\Sigma \Lambda / \Sigma \Lambda) \)). This lifts to \( f_{k-2} \). But from the 4-th invariant, we know that \( H_{k-2} \) works for the \( z = 0 \) part. Eventually, lifting this using Claim 4.2, the final hitting set (in \( x \)) will be \( H := \bigcup_{j \in [k-1]} H_j \). We remark that we do not need extra hitting set for each \( t_{k-j,j} \), because it is already covered by \( H_{k-1} \). We have also kept track of \( \text{deg}(z) \) which is bounded by \( s^{O(k)} \). We use a trivial hitting set for \( z \) which does not change the size.

Thus, we have successfully constructed a \( s^{O(k^2 \log \log s)} \times \text{time hitting set for } \Sigma [k] \Pi \Sigma \).

Remark. This is a PIT for \( \text{Gen}(k,s) \), and that too for any field of characteristic \( = 0 \) or \( \geq d \).

4.2. Border PIT for log-variate depth-3 circuits. In this section, we prove Theorem 1.3. This proof is dependent on adapting and extending [49] proof, by showing that there is a \( \text{poly}(s) \)-time hitting set for log-variate \( \Sigma \Lambda \Sigma \)-circuits.

**Theorem 4.3** (Derandomizing log-variate \( \Sigma \Lambda \Sigma \)). There is a \( \text{poly}(s) \)-time hitting set for \( n = O(\log s) \) variate \( \Sigma \Lambda \Sigma \)-circuits of size \( s \).

**Proof sketch.** Let \( g = f + \varepsilon \cdot q \), such that \( g \in \Sigma \Lambda \Sigma \), over \( \mathbb{F}(\varepsilon) \), approximates \( f \in \Sigma \Lambda \Sigma \). The idea is the same as [49]— (1) show that \( f \) has \( \text{poly}(s,d) \) partial derivative space, (2) low partial derivative space implies low cone-size monomials, (3) we can extract low cone-size monomials efficiently, (4) number of low cone-size monomials is \( \text{poly}(sd) \)-many.

We remark that (2) is direct from [47, Corollary 4.14] (with origins in [50]); see Theorem 2.2. (4) is also directly taken from [49, Lemma 5] once we assume (1); for the full statement we refer to Lemma 2.3.

To show (1), we know that \( g \) has \( \text{poly}(s,d) \) partial-derivative space over \( \mathbb{F}(\varepsilon) \). Denote

\[ V_\varepsilon := \left\langle \frac{\partial g}{\partial x^a} \mid a < \infty \right\rangle_{\mathbb{F}(\varepsilon)}, \quad \text{and} \quad V := \left\langle \frac{\partial f}{\partial x^a} \mid a < \infty \right\rangle_{\mathbb{F}}. \]

Consider the matrix \( M_\varepsilon \), where we index the rows by \( \partial x^a \), while columns are indexed by monomials (say supporting \( g \)), and the entries are the operator-values. Suppose, \( \dim(V_\varepsilon) = r \leq \text{poly}(s,d) \) (because of \( \Sigma \Lambda \Sigma \)). That means, any \((r+1)\)-many polynomials \( \frac{\partial g}{\partial x^a} \) are linearly independent. In other words, determinant of any \((r+1) \times (r+1) \) minor of \( M_\varepsilon \) is 0. Note that \( \lim_{\varepsilon \to 0} M_\varepsilon = M \), the corresponding partial-derivative matrix for \( f \). Crucially, the zeroness of the determinant of any \((r+1) \times (r+1) \) minor of \( M_\varepsilon \) translates to the corresponding \((r+1) \times (r+1) \) submatrix of \( M \) as well [one can also think of \( \text{det} \) as a “continuous” function, yielding this property]. In particular, \( \dim(V) \leq r \leq \text{poly}(s,d) \).

Finally, to show (3), we note that the coefficient extraction lemma [49, Lemma 4] also holds over \( \mathbb{F}(\varepsilon) \). Thus, given the circuit of \( g \), we can decide whether the coefficient of \( m =: x^a \) is zero or not, in \( \text{poly}(\text{cs}(m),s,d) \)-time; see Lemma 2.4. Note: the
We only extract monomials with cone-size \( \text{poly}(s, d) \) (property (2)) and there are only \( \text{poly}(s, d) \) many such monomials. Therefore, we have a \( \text{poly}(s) \)-time hitting set for \( \Sigma \Lambda \Sigma \). \( \square \)

Once we have Theorem 4.3, we argue that this polynomial-time hitting set can be used to give a poly-time hitting set for \( \Sigma^{[\ell]} \Pi \Sigma \). We restate Theorem 1.3 with proper complexity below.

\[
\text{Theorem 4.4 (Efficient hitting set for log-variate } \Sigma^{[\ell]} \Pi \Sigma \text{). There exists an explicit } s^{O(k^7)} \text{-time hitting set for } n = O(\log s) \text{ variate, size-} s, \Sigma^{[\ell]} \Pi \Sigma \text{ circuits.}
\]

\textbf{Proof sketch.} We proceed similarly as in subsection 4.1, with same notations. The reduction and branching out remains exactly the same; in the end, we get that \( f_{k-1} \in (\Pi \Sigma/\Pi \Sigma) \cdot (\text{ARO}/\text{ARO}) \). Crucially, observe that this ARO is not a generic poly-sized ARO; these AROs are de-bordered log-variate \( \Sigma \Lambda \Sigma \) circuits. From Theorem 4.3, we know that there is a \( s^{O(k^7)} \)-time hitting set (because of the size blowup, as seen in section 3). Combining this hitting set with \( \Pi \Sigma \)-hitting set is easy, by Lemma 2.28.

Moreover, \( t_{x-j, i} \) are also of the form \((\Pi \Sigma/\Pi \Sigma) \cdot (\text{ARO}/\text{ARO})\), where again these AROs are de-bordered log-variate \( \Sigma \Lambda \Sigma \) circuits and \( s^{O(k^7)} \)-time hitting set exists. Therefore, take the union of the hitting sets (as before), each of size \( s^{O(k^7)} \). This gives the final hitting set which is again \( s^{O(k^7)} \)-time constructible! \( \square \)

5. Gentle leap into depth-4: De-bordering \( \Sigma^{[\ell]} \Pi \Sigma \Lambda \) circuits. The main content of this section is to sketch the de-bordering theorem for \( \Sigma^{[\ell]} \Pi \Sigma \Lambda \). We intend to extend \( \text{DiDIL} \) and induct on the bloated model, as sketched in subsection 1.4.

\textbf{Theorem 5.1 (}\( \Sigma^{[\ell]} \Pi \Sigma \Lambda \) upper bound). Let \( f(\mathbf{x}) \in \mathbb{F}[x_1, \ldots, x_n] \), such that \( f \) can be computed by a \( \Sigma^{[\ell]} \Pi \Sigma \Lambda \)-circuit of size \( s \). Then \( f \) is also computable by an \( \text{ABP} \) (over \( \mathbb{F} \)), of size \( s^{O(k^7)} \).

\textbf{Proof sketch.} We will go through the proof of Theorem 3.2 (see section 3), while reusing the notations, and point out the important maneuvering for \( \text{DiDIL} \) to work on this more general bloated-model \((\Pi \Sigma /\Pi \Sigma \Lambda)(\Sigma \Lambda \Sigma /\Sigma \Lambda \Sigma \Lambda)\).

\textbf{Base case.} The analysis remains unchanged. We merely have to de-border \( \Pi \Sigma \Lambda \) and \( \Sigma \Lambda \Sigma \Lambda \) for numerator and denominator separately using Lemma 2.22 and Lemma 2.24. Then use the product lemma (Lemma 2.21) to conclude:

\[
(\Pi \Sigma \Lambda /\Pi \Sigma \Lambda) \cdot (\Sigma \Lambda \Sigma \Lambda /\Sigma \Lambda \Sigma \Lambda) \subseteq (\Pi \Sigma \Lambda /\Pi \Sigma \Lambda) \cdot (\text{ARO}/\text{ARO}) \subseteq \text{ABP}/\text{ABP}.
\]

Reducing the problem to \( k-1 \). To facilitate \( \text{DiDIL} \), we use the same \( \Phi : \mathbb{F}(\varepsilon)[\mathbf{z}] \rightarrow \mathbb{F}(\varepsilon)[\mathbf{z}] \); since \( \alpha_i \) are \textit{random}, the bottom \( \Sigma \Lambda \) circuits are ‘invertible’ (mod \( z^\varepsilon \)). By similar argument, it suffices to upper bound \( \Phi(f) \).

We will apply again divide and derive to reduce the fanin step by step. We just need to understand \( T_{i,j} \). Similar to Claim 3.6, we claim the following.

\textbf{Claim 5.2.} \( T_{1,k-1} \in \Pi \Sigma /\Pi \Sigma \Lambda \cdot (\Sigma \Lambda \Sigma \Lambda /\Sigma \Lambda \Sigma \Lambda) \), an element in the ring \( R_{k-1}(\mathbf{x}, \varepsilon) \), of size at most \( s^{O(k^7)} \).

\textbf{Proof.} The main part is to show that \( \text{dlog} \) acts on \( \Pi \Sigma \Lambda \) circuits “well”. To elaborate, we note that Equation 3.3 can be written for \( \Sigma \Lambda \) circuits, giving a \( \Sigma \Lambda \Sigma \Lambda \) circuit. To elaborate, let \( A - z \cdot B =: h \in \Sigma \Lambda \), such that \( 0 \neq A \in \mathbb{F}(\varepsilon) \). Therefore,
over $\mathcal{R}_1(x)$, we have
\[
d\log(h) = -\frac{\partial_z (z \cdot B)}{A(1 - z \cdot B/A)} = -\frac{\partial_z (z \cdot B)}{A} \cdot \sum_{j=0}^{d_1-1} \left(\frac{z \cdot B}{A}\right)^j.
\]

Once we use the fact that $\Sigma \land \Sigma \land$ is closed under multiplication (Lemma 2.12), it
readily follows that $d\log((\Sigma \land \Sigma \land) \in \Sigma \land \Sigma \land$. Moreover, the derivative of $\Sigma \land \Sigma \land$ is again
a $\Sigma \land \Sigma \land$ circuit, due to easy interpolation (Lemma 2.15). Following the same proof
arguments (as for Theorem 3.2), we can establish the above claim.

It was already remarked that properties shown in subsection 2.3 hold for $\Sigma \land \Sigma \land$
circuits as well. Therefore, the rest of the calculations remain unchanged, and the
size claim holds.

Interpolation & Definite integration. It is again not hard to see that
\[
f_j/t_{k-j,j}\mid_{z=0} = \lim_{\varepsilon \to 0} \sum_{\delta \in \{k-j\}} \mathbb{F}(\varepsilon) \cdot (\Sigma \land \Sigma \land) \subseteq \text{ARO}/\text{ARO} \subseteq \text{ABP}/\text{ABP}.
\]

Here, we have used the facts that $\Sigma \land \Sigma \land$ is closed under multiplication (Lemma 2.12)
and $\Sigma \land \Sigma \land \subseteq \text{ARO}$ (Lemma 2.24). The remaining steps also follow similarly once we
have the ABP/ABP form of de-bordered expressions.

We remark that in all the steps the size and degree claims remain the same and
hence the final size of the circuit for $\Phi(f)$ immediately follows.

6. Blackbox PIT for border depth-4 circuits. The DiDIL-paradigm that
works for depth-3 circuits can be used to give hitting set for border depth-4 $\Sigma^k \Pi \Sigma \Pi^k$
and $\Sigma^k \Pi \Sigma \Pi^k$ circuits. But before that, we have to argue that we have efficient hitting
set for the wedge model $\Sigma \land \Sigma \Pi^k$, which we discuss in the next subsection. Later, we
will proof-sketch the hitting set for border bounded depth-4 circuits.

6.1. Efficient hitting set for $\Sigma \land \Sigma \Pi^k$. Forbes [48] gave quasipolynomial-time
blackbox PIT for $\Sigma \land \Sigma \Pi^k$; this was basically a rank-based method. We will make
some small observations to extend the same for $\Sigma \land \Sigma \Pi^k$ as well. We encourage inter-
ested readers to refer [48] for details. First, we need some definitions and properties.

Shifted Partial Derivative measure $x^{\leq \ell} \partial_{\leq m}$ is a linear operator first introduced
in [73, 63] as:
\[
x^{\leq \ell} \partial_{\leq m}(g) := \{x^c \partial_{\ell+}^c (g)\}_{\text{deg } x^c \leq \ell, \text{deg } x^b \leq m}.
\]
It was shown in [48] that the rank of shifted partial derivatives of a polynomial
computed by $\Sigma \land \Sigma \Pi^k$ is small. We state the result formally in the next lemma.

Consider the fractional field $\mathcal{R} := \mathbb{F}(\varepsilon)$.

Lemma 6.1 (Measure upper bound). Let $g(\varepsilon, x) \in \mathcal{R}[x_1, \ldots, x_n]$ be computable
by $\Sigma \land \Sigma \Pi^k$ circuit of size $s$. Then
\[
\text{rk} x^{\leq \ell} \partial_{\leq m}(g) \leq s \cdot m \cdot \left(\frac{n + (\delta - 1)m + \ell}{(\delta - 1)m + \ell}\right).
\]

Further they observed that, rank can be lower bounded using Trailing Monomial.
Under any monomial ordering, the trailing monomial of $g$ denoted by $TM(g)$ is the
smallest monomial in the set $\text{support}(g) := \{x^a : \text{coef}_{x^a}(g) \neq 0\}$.

Proposition 6.2 (Measure the trailing monomial). Consider $g \in \mathcal{R}[x]$. For
any $\ell, m \geq 0$,
\[
\text{rkspan} x^{\leq \ell} \partial_{\leq m}(g) \geq \text{rkspan} x^{\leq \ell} \partial_{\leq m}(TM(g)).
\]
For a large enough characteristic, lower bound on a monomial was obtained.

**Lemma 6.3 (Monomial lowerbound).** Consider a monomial \( x^a \in \mathcal{R}[x_1, \ldots, x_n] \).

Then,

\[
\text{rkspan} (x^{\leq \ell} \partial_{\leq m}(x^a)) \geq \left( \frac{\eta}{m} \right) \left( \frac{\eta - m + \ell}{\ell} \right)
\]

where \( \eta := |\text{support}(x^a)| \).

In [48] the above results were combined to show that the trailing monomial of polynomials computed by \( \Sigma \Lambda \Sigma \Pi^{[d]} \) circuits have log-small support size. Using the same idea we show that if such a polynomial approximates \( f \), then support of \( TM(f) \) is also small. We formalize this in the next lemma.

**Lemma 6.4 (Trailing monomial support).** Let \( g(\varepsilon, x) \in \mathcal{R}[x_1, \ldots, x_n] \) be computable by a \( \Sigma \Lambda \Sigma \Pi^{[d]} \) circuit of size \( s \) such that \( g = f + \varepsilon \cdot Q \) where \( f \in \mathcal{F}[x] \) and \( Q \in \mathcal{F}[\varepsilon, x] \). Let \( \eta := |\text{support}(TM(f))| \). Then \( \eta = O(\delta \log s) \).

**Proof.** Let \( x^a := TM(f) \) and \( S := \{ i \mid a_i \neq 0 \} \). Define a substitution map \( \rho \) such that \( x_i \rightarrow y_i \) for \( i \in S \) and \( x_i \rightarrow 0 \) for \( i \notin S \). It is easy to observe that \( TM(\rho(f)) = \rho(TM(f)) = y^a \). Using Lemma 6.1 we know:

\[
\text{rk}_{\mathbb{R}} y^{\leq \ell} \partial_{\leq m}(\rho(g)) \leq s \cdot m \cdot \left( \frac{\eta + (\delta - 1)m + \ell}{(\delta - 1)m + \ell} \right) =: R.
\]

To obtain the upper bound for \( \rho(f) \) we use the following claim.

**Claim 6.5.** \( \text{rk}_{\mathbb{F}} y^{\leq \ell} \partial_{\leq m}(\rho(f)) \leq R \).

**Proof.** Define coefficient matrix \( N(\rho(g)) \) with respect to \( y^{\leq \ell} \partial_{\leq m}(\rho(g)) \) as follows: the rows are indexed by the operators \( y^{\leq \ell} \partial_{\leq m} \), while the columns are indexed by the terms present in \( \rho(g) \); and the entries are the respective operator-action on the respective term in \( \rho(g) \). Note that \( \text{rk}_{\mathbb{F}(\varepsilon)} N(\rho(g)) \leq R \). Similarly define \( \mathcal{N}(\rho(f)) \) with respect to \( y^{\leq \ell} \partial_{\leq m}(\rho(f)) \), then it suffices to show that \( \text{rk}_{\mathbb{F}} \mathcal{N}(\rho(f)) \leq R \).

For any \( r > R \), let \( \mathcal{N}(\rho(g)) \) be a \( r \times r \) sub-matrix of \( N(\rho(g)) \). The rank bound ensures: \( \det \mathcal{N}(\rho(g)) = 0 \). This will remain true under the limit \( \varepsilon = 0 \); thus, \( \det(\mathcal{N}(\rho(f))) = 0 \).

Since \( r > R \) was arbitrary and linear dependence is preserved, we deduce:

\[
\text{rk}_{\mathbb{F}} N(\rho(f)) \leq R.
\]

For lower bound, recall \( y^a = TM(\rho(f)) \). Then, by Proposition 6.2 and Lemma 6.3, we get:

\[
(6.1) \quad \text{rk}_{\mathbb{F}} y^{\leq \ell} \partial_{\leq m}(\rho(f)) \geq \left( \frac{\eta}{m} \right) \left( \frac{\eta - m + \ell}{\ell} \right).
\]

Comparing Claim 6.5 and Equation 6.1 we get:

\[
s \geq \frac{1}{m} \cdot \left( \frac{\eta}{m} \right) \cdot \left( \frac{\eta - m + \ell}{\ell} \right) / \left( \frac{\eta + (\delta - 1)m + \ell}{(\delta - 1)m + \ell} \right).
\]

For \( \ell := (\delta - 1)(\eta + (\delta - 1)m) \) and \( m := \lfloor n/e^3 \rfloor \), [48, Lem.A.6] showed \( \eta \leq O(\delta \log s) \).}

Existence of a small support monomial in a polynomial, which is being approximated, is a structural result which will help in constructing a hitting set for this larger class. The idea is to use a map that reduces the number of variables to support-size, and then invoke Theorem 2.25.
THEOREM 6.6 (Hitting set for $\Sigma^{\wedge} \Pi^{[2]}$). For the class of n-variate, degree d polynomials approximated by $\Sigma^{\wedge} \Pi^{[2]}$ circuits of size s, there is an explicit set $H \subseteq \mathbb{F}^n$ of size $s^{O(\delta \log s)}$ i.e., for every such nonzero polynomial $f$ there exists an $\alpha \in H$ for which $f(\alpha) \neq 0$.

Proof. Let $g(\varepsilon, x) \in \mathcal{R}[x_1, \ldots, x_n]$ be computable by a $\Sigma^{\wedge} \Pi^{[2]}$ circuit of size s such that $g := f + \varepsilon \cdot Q$, where $f \in \mathbb{F}[x]$ and $Q \in \mathbb{F}[\varepsilon, x]$. Then Lemma 6.4 shows that there exists a monomial $x^a$ of f such that $|\text{support}(x^a)| = O(\delta \log s)$.

Let $S \in \binom{[n]}{\eta}$ Define a substitution map $\rho_S$ such that $x_i \rightarrow y_i$ for $i \in S$ and $x_i \rightarrow 0$ for $i \notin S$. Note that, under this substitution non-zeroness of f is preserved for some S, because monomials of support $S \supseteq \text{support}(x^a)$ will survive for instance. Essentially $\rho_S(f)$ is an $\eta$-variate degree-d polynomial. For which Theorem 2.25 gives a trivial hitting set of size $O(d^n)$. Therefore, with respect to S we get a hitting set $\mathcal{H}_S$ of size $O(d^n)$. To finish, we do this for all such S, to obtain the final hitting set $\mathcal{H}$ of size:

$$\binom{n}{\eta} \cdot O(d^n) \leq O((nd)^n).$$

\[\square\]

Remark 6.7. Unlike border-depth-3 PIT result, we obtain this result without derandomizing the circuit at all.

6.2. DiDIL on depth-4 models. The DiDIL-paradigm along with the branching idea, in subsection 4.1, can be used to give hitting set for border depth-4 $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$ and $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$ circuits. For brevity, we denote these two types of (non-border) depth-4 circuits by $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$ circuits where $\pi \in \{\wedge, \Pi^{[2]}\}$. We will separate hitting set for the border of each class, while analysing them together.

THEOREM 6.8 (Hitting set for bounded border depth-4). There exists an explicit $s^{O(k^2 \log \log s)}$ (respectively $s^{O(k \log \log \log s)}$)-time hitting set for $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$ (respectively $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$)-circuits of size s.

Proof sketch. We will again follow the same notation as subsection 4.1. Let $g_0 := \sum_{i \in [k]} T_{i, 0} = f_0 + \varepsilon S_0$ such that $g_0$ is computable by $\Sigma^{[k]} \Pi^{\wedge} \Pi^{[2]}$ over $\mathbb{F}(\varepsilon)$. As earlier, we will instead work with bloated model that preserves the structure on applying the DiDiL technique. The bloated model we consider is

$$\Sigma^{[k]} (\Pi^{\wedge} \Pi^{[2]}) (\Sigma^{\wedge} \Sigma^{[2]} / \Sigma^{\wedge} \Sigma^{[2]}).$$

Define a map $\Phi : \mathbb{F}(\varepsilon)[x] \rightarrow \mathbb{F}(\varepsilon)[x, z]$ such that $x_i \rightarrow z \cdot x_i + \alpha_i$. Essentially, our $\Sigma^{\wedge} \Sigma^{[2]}$ circuits are at most $s$-sparse, so it suffices to consider the sparse-PIT [76], yielding a different $\Phi$. The invertible map implies: $f_0 \neq 0$ if and only if $\Phi(f_0) \neq 0$.

The next steps are essentially the same: reduce $k$ to the bloated $k - 1$, and inducively to the bloated $k = 1$ case. There will be `branches' for each branch we will give efficient hitting sets; taking their union will give the final hitting set.

By Divide and Derive, we will eventually show that

$$f_0 \neq 0 \iff f_{k-1} \neq 0 \text{ over } \mathcal{R}_j(x), \text{ or } \bigvee_{i=1}^{k-2} (f_i/t_{k-1-i} | z = 0 \neq 0 \text{ over } \mathbb{F}(x)).$$

$T_{1, k-1} \in (\Pi^{\wedge} \Pi^{[2]}) (\Sigma^{\wedge} \Sigma^{[2]} / \Sigma^{\wedge} \Sigma^{[2]})$, over $\mathcal{R}_{k-1}(x, \varepsilon)$, similar to Claim 5.2. The trick is again to use dlog and show that $d\log(\Pi^{\wedge} \Pi^{[2]}) \in \Sigma^{\wedge} \Sigma^{[2]}$. However the size blowup behaves slightly differently. We point this out in the next claim.
Claim 6.9. For $\Sigma^k[\Pi \Sigma \Lambda]$, respectively $\Sigma^k[\Pi \Sigma \Pi \delta]$, we have

$$T_{1,k-1} \in \left( \frac{\Pi \Sigma \Lambda}{\Pi \Sigma \Lambda} \right) \cdot \left( \frac{\Sigma \Lambda \Sigma \Lambda}{\Sigma \Lambda \Sigma \Lambda} \right) \text{respectively} \left( \frac{\Pi \Sigma \Pi \delta}{\Pi \Sigma \Pi \delta} \right) \cdot \left( \frac{\Sigma \Lambda \Sigma \Pi \delta}{\Sigma \Lambda \Sigma \Pi \delta} \right),$$

over $R_{k-1}(x, \varepsilon)$ of size $s^{O(k^7)}$ respectively $(s^3)^O(k^7)$. 

Proof sketch. We explain it for one step i.e. over $R_1(x, \varepsilon)$. Let $A - z \cdot B = h \in \Sigma \Upsilon$, such that $A \in \mathbb{F}(\varepsilon)$ (we have already shifted). Therefore, over $R_1(x)$, we have

$$\log(h) = -\frac{\partial_z (z \cdot B)}{A (1 - z \cdot B/A)} = -\frac{B}{A} \cdot \sum_{j=0}^{d-1} \left( \frac{z \cdot B}{A} \right)^j.$$

Here, use the fact that $\Sigma \Lambda \Sigma \Upsilon$ is closed under multiplication. For $\Sigma \Lambda \Sigma \Lambda$ circuits, the calculations remain the same as in section 5. However, for $\Sigma \Lambda \Sigma \Pi \delta$ circuits, note that as $h$ is shifted, size($B$) is no longer poly(s); but it is at most $3^\delta \cdot s$, see Claim 2.20. Therefore, the claim follows. 

Eventually, one can show (using Lemma 2.21 to distribute):

$$f_{k-1} \in (\Pi \Sigma \Upsilon / \Pi \Sigma \Upsilon) \cdot (\Sigma \Lambda \Sigma \Upsilon / \Sigma \Lambda \Sigma \Upsilon) \subseteq (\Pi \Sigma \Upsilon / \Pi \Sigma \Upsilon) \cdot (\Sigma \Lambda \Sigma \Upsilon / \Sigma \Lambda \Sigma \Upsilon).$$

When $\Upsilon = \Lambda$, we know $\Sigma \Lambda \Sigma \Lambda \subseteq \text{ARO}$ and thus this has a hitting set of size $s^{O(k^7 \log \log s)}$ (Theorem 2.27). We also know hitting set for $\Pi \Sigma \Lambda$ (Theorem 2.26).

Combining them using Lemma 2.28, we have a quasipolynomial-time hitting set of size $s^{O(k^7 \log \log s)}$.

As seen before, we also need to understand $z = 0$ evaluation. By similar argument, it will follow that

$$f_j/t_{k-j,j}|_{z=0} \in \lim_{\varepsilon \to 0} \sum_{i=|k-j|} \mathbb{F}(\varepsilon) \cdot (\Sigma \Lambda \Sigma \Upsilon / \Sigma \Lambda \Sigma \Upsilon) \subseteq \Sigma \Lambda \Sigma \Upsilon.$$

When $\Upsilon = \Lambda$, we can de-border and this can be shown to be an ARO. Thus, in that case $f_j/t_{k-j,j}|_{z=0} \in \text{ARO/ARO}$, where hitting set is known (similarly as before) giving hitting set for each branch. Once we have hitting set for each branch, we can take union (similar to Claim 4.2) to finally give the desired hitting set.

Unfortunately, we do not know $\Sigma \Lambda \Sigma \Upsilon$, when $\Upsilon = \Pi[0]$, as the duality trick cannot be directly applied. However, as we know hitting set for $\Sigma \Lambda \Sigma \Pi[0]$, from Theorem 6.6, we will use it to get the final hitting set. To see why this works, note that we need to ‘hit’ $f_{k-1} \in (\Pi \Sigma \Pi[\delta] / \Pi \Sigma \Pi[\delta]) \cdot (\Sigma \Lambda \Sigma \Pi[\delta] / \Sigma \Lambda \Sigma \Pi[\delta])$. We know hitting sets for both $\Pi \Sigma \Pi[\delta]$ (Theorem 2.26) and $\Sigma \Lambda \Sigma \Pi[\delta]$ (Theorem 6.6), thus combining them is easy.

To get the final estimate, define $s' := s^{O(\delta k^7)}$; which signifies the size blowup due to DiDIL. Next, the hitting set $H_{k-1}$ for $f_{k-1}$ has size $(n d)^{O(\delta \log \log s')} \leq s^{O(\delta^7 k^7 \log \log s')}$. We know that similar bound also holds for each branch. Taking their union gives the final hitting set of the size as claimed.

7. Conclusion & future direction. This work introduces the DiDIL-technique and successfully de-borders as well as derandomizes $\Sigma^k[\Pi \Sigma]$. Further we extend this to depth-4 as well. This opens a variety of questions which would enrich border-complexity theory.

1. Does $\Sigma^k[\Pi \Sigma] \subseteq \Sigma \Pi \Sigma$, or $\Sigma^k[\Pi \Sigma] \subseteq \text{VF}$, i.e. does it have a small formula?

2. Can we show that $\text{VBP} \neq \Sigma^k[\Pi \Sigma]$? 1

1Very recently, Dutta and Saxena [39] showed an exponential gap between the two classes.
3. Can we improve the current hitting set of \( s^{\exp(k) \cdot \log \log s} \) to \( s^{O(\text{poly}(k) \cdot \log \log s)} \), or even a poly(s)-time hitting set? The current technique seems to blow up the exponent.

4. Can we de-border \( \Sigma \land \Pi^k \), or \( \Sigma^k \land \Pi \land \Pi^k \), for constant \( k \) and \( \delta \)? Note that we already have quasi-derandomized the class (Theorem 6.8).

5. Can we show that constant border-waring rank is polynomially bounded by waring rank, the degree and the number of variables? i.e. \( \Sigma^k \land \Sigma \subseteq \Sigma \land \Sigma \) for constant \( k \)?

6. Can we de-border \( \Sigma^{k^2} \land \Pi \land (\Sigma^k) \) ? i.e. the bottom-layer has variable mixing.

**De-bordering vs. Derandomization.** In this work, we have successfully de-bordered and (quasi)-derandomized \( \Sigma^k \Pi \Sigma \). Here, we remark that de-bordering did not directly give us a hitting set, since the de-bordering result was more general than the models where explicit hitting sets are known. However, we were still able to do it because of the DiDIL-technique. Moreover, while extending this to depth-4, we could quasi-derandomize \( \Sigma^k \Pi \Sigma \Pi^k \), because eventually hitting set for \( \Sigma \land \Sigma \Pi \) is known. However we could not de-border \( \Sigma \land \Sigma \Pi^k \), because the duality-trick fails to give an ARO. This whole paradigm suggests that de-bordering may be harder than its derandomization.
